Definition

Punitive sentiment is the desire to harm someone because of their behavior or because of their relative status.

Introduction

Punitive sentiment is the desire to harm someone – even when doing so incurs a personal cost to the punisher (Clutton-Brock and Parker [1995](#); Raihani et al. [2012](#)). Punishment can be aimed at cheats in social interactions – this is typically called “responsible” or “justified” punishment. Punishment can also be aimed at cooperative, or helpful individuals, or meted out by the cheating individuals themselves – this is typically called “antisocial punishment” (Herrmann et al. [2008](#); Sylwester et al. [2013](#)). (Henceforth, the word “punishment” refers only to responsible or justified punishment.) Administering punishment is costly to the punisher as well as to the target. To understand how punitive sentiment could be favored by natural selection, one therefore has to ask how punishers ultimately derive benefits from these investments. I will outline the various

explanations that have been proposed to account for the adaptive significance of punishment.

How does Punishment Evolve?

Several possible solutions have been proposed to resolve the puzzle of how costly punishment can be favored by selection. In repeated two-player settings, punishment can theoretically evolve via direct-within interaction benefits to punishers, when targets behave more cooperatively with punishers after being punished (Clutton-Brock and Parker 1995; Price et al. 2002; Raihani et al. 2012). Nevertheless, in humans, this theoretical prediction lacks clear empirical support. Rather, many studies have shown that punishment does not necessarily induce targets to cooperate (Barclay and Raihani 2016; Bone et al. 2015, 2016b; Dreber et al. 2008; Nikiforakis and Engelmann 2011) and can even prompt counter-punishment (Balafoutas et al. 2014; Bone et al. 2015, 2016b; Dreber et al. 2008; Fehr et al. 2012; Nikiforakis 2008; Nikiforakis and Engelmann 2011), thereby further increasing the costs associated with punishment. Moreover, punishment in multiplayer settings and in one-shot interactions is harder to explain. In multiplayer interactions, non-punishing free-riders can reap the benefits of punishment without contributing to the cost, thereby creating a second-order social dilemma (Yamagishi 1986). In one-shot interactions, or in interactions where the punisher was not the victim of the cheat and does not expect to interact with the target in future, then punishers by definition cannot benefit from an improvement in the target's behavior in future interactions. How, then, does punishment evolve in these more puzzling scenarios?

Group-Selection Accounts of Punishment

In principle, punishment in multiplayer and/or one-shot settings could evolve via group level selection. Two different versions of the group selection explanation exist, which imply competition between genes and between cultural memes within a population, respectively. Both versions of group selection invoke the assumptions that

between-group competition is stronger than competition within groups, that groups with punishers outperform groups without punishers, and that variance among (genetic or cultural) groups is higher than variance within them (see Raihani and Bshary (2015c) for further discussion). These assumptions do not have unanimous empirical support (see, for example Lamba and Mace 2011; Yamagishi and Mifune 2016).

Under genetic group selection, punishment would be personally costly to punishers but could theoretically evolve via benefits to the punisher's kin, if these benefits depended on the success of the punisher's group in competition with other groups. The mathematics of evolution via kin selection and via genetic group selection are formally equivalent (Gardner 2008; West et al. 2011). Nevertheless, the circumstances under which genetic group selection could be an important force are thought to be extremely uncommon in human societies (see Bell et al. 2009; Seielstad et al. 1998), and theoretical models have shown that increasing relatedness among group members hinders the evolution of punishment via kin-based benefits (Gardner and West 2004), rather than increasing it as would be expected under a genetic group selection account.

A cultural group selection account assumes that individuals have higher cultural (rather than genetic) relatedness to members of their group than to outgroup members. This means that individuals have a higher probability of sharing the same memes with members of their cultural groups than they do with other randomly selected members of the population. High levels of cultural relatedness can be generated by predispositions to copy other group members – under the assumption that copying can be adaptive when the costs of information gathering are high (e.g., Boyd and Richerson 1982; but see Andre and Morin 2011). Selection acting on cultural, rather than genetic, variation between groups might in principle be more realistic since between-group differences in culture can be maintained if immigrating individuals adopt the norms and memes of their new group. Theoretical work has shown how punishment can be sustained in a population (via payoff-based imitation) when it is already common in

the population (Boyd et al. 2003). Note, however, that a high frequency of punishers in a population indicates that cooperation will also be high – and thus the costs associated with punishing are seldom incurred. It is far less clear how punishment could invade a similar population comprised mostly of nonpunishing defectors (Lehmann et al. 2007) – here punitive strategies would be (possibly prohibitively) expensive and, if rare, would not be expected to spread via imitation. Indeed, more recent theoretical work has shown that strategically nonconforming strategies are expected to dominate over strategies that blindly conform to payoff-reducing behaviors (e.g., Morin 2014; Mouden et al. 2014).

“Big-Mistake” Explanations of Punishment

An alternative explanation is that investment in costly punishment in one-shot interactions stems from the misfiring of psychological mechanisms that instead evolved in the context of repeated interactions, where punishment would have been under positive, individual-level selection. In other words, punishment in one-shot interactions can be viewed as a “big mistake” – the right behavior deployed in the wrong setting (see Raihani and Bshary (2015c) for description and critique). For instance, one recent study found that investment in third-party punishment was determined by the extent to which subjects inferred mistreatment of another individual predicted that the protagonist would also mistreat them (Krasnow et al. 2016). Thus, third-party punishment is predicated on an expectation that the punisher will interact with the target of punishment in future. The authors argue that this expectation would have been reasonable in the ancestral environment where these sentiments evolved, since one-shot interactions with unknown individuals would have been uncommon. The assumptions that one-shot interactions were indeed uncommon and that ancestral humans are unable to distinguish between interactions that are likely to be repeated or ones where there is no obvious future have been challenged, however (e.g., see Lamba and Mace (2010) and Raihani and Bshary (2015c) for a

review); as has the implicit assumption that we are unable to rapidly adapt to changing social circumstances (e.g., Rand 2016).

Individual-Level Benefits of Punishment

More recent studies have started to explore alternative explanations for the evolution of punishment in otherwise puzzling scenarios. One major route by which punishment could evolve without recourse to kin-selected benefits, spatial assortment, or between-group competition is by relaxing the assumption that the benefits of punishment are a linear function of investments (Raihani and Bshary 2011). Where the benefits of punishment scale nonlinearly with investments, then the dilemma more closely approximates an n-player snowdrift game (a volunteer’s dilemma, Diekmann 1993) than an n-player prisoner’s dilemma game. Relaxing the assumption of linearity has profound consequences for the evolution of costly social behavior – here, an evolutionarily stable strategy (ESS) can be to invest probabilistically rather than to always defect (the latter being the only ESS in a one-shot, n-player prisoner’s dilemma (Archetti and Scheuring 2012)). In nonlinear public goods games, the invasion of punishment does not depend on social learning and copying – punitive strategies can therefore invade when they are initially rare in a population (e.g., see Boyd et al. (2010), which is discussed in light of nonlinear payoffs in Raihani and Bshary (2011)).

Another, nonmutually exclusive possibility is that punishment yields direct reputation-based benefits to punishers (Barclay 2006; Raihani and Bshary 2015a). These benefits can arise if observers cooperate because they wish to avoid being targeted for punishment (e.g., Santos and Wedekind 2015; Santos et al. 2011, 2013) or because punishment acts as an honest signal of the punisher’s other-regarding preference or cooperative intent. In the latter scenario, punishers benefit because they are more likely to be trusted (Barclay 2006; Jordan et al. 2016), rewarded by others (Raihani and Bshary 2015b), or preferred as interaction partners (Raihani and Bshary 2015a). A signaling account of punishment can

explain the tendency to punish in seemingly anonymous one-shot encounters without invoking the assumption that punishers expect to interact with the target of punishment in the future. Rather, if the benefit of acquiring a punitive reputation outweighs the costs associated with punishing, then signaling punishment could in principle be favored by selection (Jordan and Rand 2017; Raihani and Bshary 2015a; Santos and Wedekind 2015).

A final possibility is that punishers benefit because they increase their fitness relative to that of targets. This is the case whenever it costs less to administer punishment than it does to receive it. Competition for status (in terms of payoffs not reputation) may indeed be an important function behind antisocial punitive sentiment (Bryson et al. 2014; Sylwester et al. 2013): previous studies have shown that when the fee to fine ratio of punishment is increased to 1:1 or greater, then antisocial punishment is markedly reduced (Falk et al. 2005). The extent to which competition for status (in terms of increased payoffs, rather than reputation) also explains some variation in justified punishment remains an open question.

How Is Punishment Studied in the Lab?

In lab studies, punishment is typically operationalized by allowing individuals to pay a (monetary) fee to exact a fine on a cheating individual (e.g., Fehr and Gächter 2002). Typically, the cost to the punisher is assumed to be lower than the cost to the target (the most commonly used ratio is 1: 3) although it is not obvious that this assumption would necessarily hold in real-world interactions, where players might often vary in their ability to mete out and sustain the costs of punishment (Raihani et al. 2012). Though humans are often willing to pay to impose costs on coplayers in these stylized experimental scenarios, it is unclear what behavior this captures in the real-world interactions (Guala 2012), particularly in industrialized societies, where punishment tends to be administered by legitimate centralized authorities, rather than by peers of the target (Baldassarri and Grossman 2011). Evidence for peer punishment has been

observed in smaller-scale societies (e.g., Mathew and Boyd 2011), but real-world evidence for peer punishment in industrialized societies is relatively scarce. Despite the uncertainty over the real-world behaviour that lab punishment maps onto, studying punishment in lab settings can be useful if it allows researchers to identify the situational or proximate factors which elicit punitive sentiment. By identifying the scenarios that reliably motivate punishment in the lab, we may be able to gain insights into the ultimate (evolved) function of punitive sentiment (Price et al. 2002).

Motives Underpinning Punishment

Previous studies have shown that interacting with a cheat produces feelings such as anger, disgust, and envy (Fehr and Gächter 2002; Pedersen et al. 2013), and that being allowed to punish the cheating individual (usually by paying a small fee to exact a larger fine on the cheat), individuals experience relief from these negative feelings and may even derive subjective pleasure from the punitive act (De Quervain et al. 2004). Investing in third-party punishment, where the punisher intervenes on behalf of another individual (Fehr and Fischbacher 2004), is also subjectively rewarding for punishers (Buckholtz et al. 2008).

Though interacting with cheats can elicit punitive sentiment, the precise cause of these feelings remains debated. In most laboratory settings, individuals that interact with cheats incur losses and experience disadvantageous inequity, in that they end up with lower payoffs than the cheat (Dawes et al. 2007; Raihani and McAuliffe 2012). Thus, punitive sentiment could feasibly arise from either the negative utility associated with experiencing losses (i.e., revenge-based motives) or from the negative utility of experiencing disadvantageous inequity (i.e., fairness concerns). These two potentially separate motives for punishment also suggest alternative evolved functions for punishment, with revenge-based motives being more consistent with a deterrent function of punishment and fairness concerns being more consistent with a fitness-levelling function of punishment (Bone and Raihani 2015; McCullough et al. 2013; Price et al. 2002).

Punitive Sentiment Reflects Fairness Concerns

Early attempts to tease these two possibilities apart found that when losses are held constant (see Bone and Raihani 2015; Bone et al. 2016a; Raihani and McAuliffe 2012), or are not a feature of the interaction (Dawes et al. 2007) then punishment is most common when the punisher has lower payoffs than the target. Preferences for equality are also a reliable predictor of investment in costly punishment in public goods games (Johnson et al. 2009) and that third-party punishment is more likely to reflect envy than moralistic anger on the part of the punisher (Leibbrandt and Lopez-Pérez 2011, 2014; Pedersen et al. 2013). When possible, punishers typically tailor their investment in punishment to equalize payoffs between themselves and the target (Bone and Raihani 2015) and will even invest in punishment when these actions will not be communicated to the target (thereby preventing any deterrence-based benefits (Crockett et al. 2014)). Finally, when given the option to compensate themselves or a third-party without additionally punishing a cheat, most subjects choose this option (Charness et al. 2008; Chavez and Bicchieri 2013; FeldmanHall et al. 2014; Lotz et al. 2011), suggesting that when alternative means to establish fairness are possible, then punitive sentiment decreases. Together, these many and varied findings suggest an important role of fairness concerns (synonymous with feelings of envy or disadvantageous inequality aversion) are an important proximate motive underpinning punishment decisions in humans.

Punitive Sentiment Reflects Desire for Revenge

Though the importance of fairness concerns is apparent, based on the empirical literature above, other studies have also emphasized the role of revenge in producing punitive sentiment. For instance, when individuals only have access to inefficient punishment (which doesn't allow punishers to redress disadvantageous inequity), they

still punish cheats (Bone and Raihani 2015), mitigating against fairness concerns as the sole underlying cause of punitive sentiment. Moreover, Marczyk (Marczyk 2017) showed that only inequality paired with losses motivated punishment – inequality that was produced without harming the other player did not motivate punishment (but see Dawes et al. (2007) for contrasting evidence).

Conclusion

Punishment has been well studied in laboratory games – where several studies have shown that people are willing to forfeit their own resources to take resources from another player. Punitive sentiment is apparently caused by a desire for revenge, fairness concerns, and a desire to elevate payoffs relative to that of the target. Enacting punishment yields subjective rewards. Despite the many lab-based studies, the prevalence of punishment in the real world seems scarce. Thus, a clear avenue for further research is to ask how the punitive sentiment we observe in the lab manifests in the real world.

Mechanisms of altruism

Definition

There are different evolutionary mechanisms such as kin selection, reciprocal altruism, and cultural

group selection that explain the mechanisms of altruism commonly seen in human societies.

From an evolutionary perspective, a behavior is called social if it influences the fitness of both the actor and the recipient (West et al. 2007). William Hamilton (1964) classified social behaviors into four types: those that increase the fitness of both the actor and the recipient (mutual benefit), those that increase the fitness of the actor but decrease that of the recipient (selfishness), those that decrease the fitness of the actor but increase that of the recipient (altruism), and those that decrease the fitness of both the actor and the recipient (spite). The most puzzling seems to be altruism because even spite might have a relatively straightforward explanation: An actor might gain a foothold by a fitness decreasing behavior if it decreases the fitness of a rival even more. Therefore, most effort in social evolution theory in the last half-century went into developing evolutionary explanations of altruistic behavior.

Hamilton proposed kin selection as one mechanism through which natural selection can favor altruism over selfishness: If the actor and the recipient of the altruistic behavior are genetic relatives, the altruistic behavior is actually helping the survival of the altruist's genes. More precisely, altruistic behavior will evolve if the coefficient of genetic relatedness, r , exceeds the cost-benefit ratio of the altruistic behavior, c/b (see also Nowak 2006).

The first solution to altruism among nonrelatives was proposed by Trivers (1971) in his theory of reciprocal altruism: If the actor behaves altruistically toward the recipient in need at time t_1 , and the recipient returns the favor when the actor is in need at time t_2 , then both of them will be better off compared to the situation where neither behaved altruistically. The obvious threat to the evolution of altruism through reciprocal altruism is the possibility of cheating: taking the benefit at t_1 but never returning it. Since this is evolutionarily the most beneficial strategy, altruism cannot evolve unless cheating is prevented. For this reason, relatively complex cognitive skills, such as memory for past exchanges and mind reading skills for recognizing potential cheaters, must be in place before reciprocal altruism can lead to the

evolution of altruistic behavior (see Stevens and Hauser 2004).

In reciprocal altruism, reciprocity is direct: The same actor and recipient are involved in both interactions. Indirect reciprocity, on the other hand, involves the introduction of third parties at time t_2 and is based on the principle of reputation. By behaving altruistically at time t_1 , the actor gains a reputation in the population of being an altruist. This will increase his chances of receiving altruistic benefits from other members of the population at a later time because of his reputation of being a suitable cooperation partner (Nowak and Sigmund 1998).

One final mechanism proposed to solve the puzzle of the evolution of altruism is cultural group selection (Fehr and Fischbacher 2003). Economic exchange games played in the laboratory demonstrate that humans cooperate altruistically even when their game partners are nonrelatives (excluding kin selection as a mechanism), when the game is one shot with no future interactions (excluding reciprocal altruism), and when the game is played anonymously with no possibility of reputation building (excluding indirect reciprocity). Even under such conditions, at least some individuals display altruistic rewarding (rewarding fair and norm-compliant behavior even when the rewarding is costly to the actor) and altruistic punishment (punishing unfair behavior even when the punishment is costly to the actor). It has been claimed that stronger reciprocators, those who use altruistic rewarding and punishment, are at a disadvantage as individuals compared to selfish individuals; however, a group composed of strong reciprocators will be more likely to survive than a group composed of selfish individuals. Thus, altruism in the form of strong reciprocity has most likely evolved through the mechanism of cultural group selection. This proposal is controversial (see West et al. 2011), and it

remains to be seen whether individual selection mechanisms will suffice to explain strong reciprocity.

Q

Qualitative Versus Quantitative in Evolutionary Science

Quantitative data are analyzed using statistical techniques which summarize the data and supply inferential reports on the relationships between quantized variables. These can include such things as correlation coefficients, effect sizes, *p* values, odds ratios, and often (but not always) make use of the properties of the general linear model (Grafen and Hails 2002).

Definition

Qualitative data are necessarily subjective, being filtered through the medium of a human consciousness. Techniques for collecting these include interviews, ethnography, observations, or clinical reports. Resultant data are analyzed using techniques such as discourse analysis, thematic analysis, or interpretive phenomenological analysis. Goals of analysis include the triangulation of diverse viewpoints, and, arguably, aim at *saturation* – a state where enough iterative analysis has been performed, that the same themes now keep recurring (Willig 2013).

Quantitative data are numbers. They are collected through such activities as observations, questionnaires using numerical scales, and direct measurements of behavior, or physiology.

Introduction

Obviously, analysis of both sorts of data are searches for meaning, but meaning of rather different kinds. Qualitative data analyses expressly dig into the meanings that a person, or group, gives to events and experiences (e.g. Dempsey et al. 2019). Quantitative data try to go beyond mere numerical counts, to express confidence about the degree of relationship between variables. The ideal is to provide causal explanation, but this is rarely, if ever, achieved in behavioral science.

Quantitative data are often considered objective, but, once one appreciates that one can quantize subjective impressions, via Lickert scales, for example, then this cannot be the primary distinction between the two types of data. Quantitative data are numbers, and numbers, unless one is a mathematical Platonist, are *adjectives of quantity*, rather than reality itself. Thus, numbers (or rather, numerically operationalized behavioral data, or psychological constructs) can be compared with

degrees of rigor, and abstraction unavailable to qualitative data, but it does not follow that they are thereby more scientific. This may appear heretical to some people, but such people are confused by one of two things: Physics Envy or the Drunkards Search Principle.

The Art or The Real?

Physics Envy is a misplaced desire for elegance in explanation. In physics (but only here), elegance *is* one guide to truth. However, evolution is a series of messy kludges that maximizes fitness, without achieving perfection. Evolved solutions to fitness problems usually involve things like opponent processes that maximize fitness by achieving homeostasis or similar balances and trade-offs in an organism. Thus the ideal of elegant equations to explain human behavior is likely to be a wild goose chase (Minsky 1988).

The drunkard searches under a streetlight for his keys, not because they are there, but because the light is better there. Scientists also tend to search the data in places where their techniques work. However, theory, not technique, should govern what questions we ask of the data (Cronbach and Meehl 1955).

Subjectivity can appear messy, and unscientific, compared to counting. Is it true that qualitative research is synonymous with a postmodernist relativistic anti-science position? Although there is evidence of a specifically qualitative-based opposition to evolutionary principles (Jonason and Schmitt 2016), we argue that this antipathy is both misplaced and unnecessary. Both types of analysis can be done well or poorly, with rigor, or not. There is nothing unscientific about acknowledging that humans have minds. Deflationary accounts of psychology – such as extreme behaviorism – seek to downplay or eliminate consciousness from casual explanations. However, there is no compelling reason for evolutionary scholars to feel impelled down this path. Nature does not give free lunches, and subjective consciousness would be, if it were causally impotent, the most

lavish of all free lunches. Thus, evolutionary scholars should, on pain of incompleteness, find a place for causally efficacious consciousness in their science. There are various ways in which this heterophenomenology might be achieved (Dennett 2003). Two obvious illustrations are provided by the study of linguistic entities and self-report.

Language is a species-typical adaptation, and (arguably) our most direct window into the subjective human psyche. Its universality supports one evolutionary psychology foundational belief – that of the psychic unity of humanity. Humans use language to (among other things) generate social selves – centers of narrative gravity. Brains model worlds and any sufficiently advanced model contains a model of itself. Humans are good at this modelling – with the appropriate caveats of Freud (2018) and Trivers (2011) whose insights into self-deception are easily accommodated within evolutionary theory – particularly evolutionary game theory. Independent validations exist of our ability to access such things as personal history, attentional focus, sensations, and evaluations, but humans are poor at accessing their own motives (Nisbett and Wilson 1977). It does not follow that they are poor at assessing one another motives, however.

Self-reports of cognitive risk are more predictive of depression and schizophrenia in a non-clinical population than any extant brain scan (Haeffel 2010). The undoubted fact that humans fool themselves (Freud 2018; Trivers 2011) does not mean that these centers of narrative gravity are not legitimate foci of scientific analysis – on the contrary, they are part of the species-typical human signaling system, and rigor in analysis of meaning-making should therefore be part of the evolutionary toolkit.

Conclusion

Subjective meaning-making is a species typical trait and deserves to be treated as such by evolutionary scholars. Said meaning-making is not the final word on predictive or descriptive accounts

of human behavior, but it can be treated with appropriate rigor, as part of the complete picture of human behavior.

Definition

The ability to represent and manipulate the approximate quantities of collections of objects.

Introduction

The behavior of a very diverse range of nonhuman species and human infants and young children indicates that they can discriminate the relative quantity of both discrete collections of objects and continuous magnitudes, such as area (Feigenson et al. 2004). Research on these systems has intensified over the past decade, as has the study of the relation between these abilities and children's learning of formal, symbolic mathematics. The primary focus has been on the ancient approximate number system (ANS) that in turn may be part of a more general magnitude processing system. In primates the systems for

magnitude processing are situated in an area of the parietal cortex called the intraparietal sulcus (IPS) and functionally integrated with areas of the prefrontal cortex during quantity discriminations (Nieder et al. 2002; Piazza et al. 2004).

The selection pressures that drove the evolution of systems for processing discrete and continuous magnitudes likely involved foraging efficiency and evaluation of social signals associated with mating competition or mate choices (Geary et al. 2015). Foraging efficiency requires searching in locations that will provide the best payoff per unit of foraging time. The payoff will necessarily be dependent on the discrete number of prey and their size (i.e., magnitude) at a particular location, as well as the time needed to capture them and the number of conspecifics (others of the same species) foraging in the same place. Selection on foraging behaviors and decisions (e.g., when to switch to a new location) will thus favor the evolution of brain and cognitive systems that can represent and operate on the number and size of prey and integrate these with a representation of time and the number of competitors for the same prey.

Traits associated with mating competition or mate choices are often exaggerated and can only be expressed by fit individuals. These mating-related traits thus signal the health and overall fitness of the individual and can include traits based on discrete number, such as frequency of mating-song bouts, or continuous magnitudes, such as the area of colorful plumage patches on birds. Across species continuous magnitude traits (e.g., area) are more common than discrete traits in mating contexts, and computational simulations suggest that the systems for representing continuous magnitudes likely evolved prior to the evolution of the ability to discriminate discrete quantities. Nevertheless, most of the research on human quantity discrimination has focused on the ANS.

The signature feature of the ANS is that its representations are inherently “noisy” – resulting in approximate representations of quantity – and this noise increases with increasing set size,

following the Weber-Fechner law (Moyer and Landauer 1967). Behaviorally, the result is that accuracy in discriminating quantities is dependent on the ratio of the quantities and not the absolute difference between them. The ability to discriminate between collections of 4 and 8 (2 to 1 ratio) objects is much easier (faster and more accurate) than between 24 and 28 (1.16 to 1 ratio) objects, even though the absolute difference is the same. For humans, the acuity of the ANS undergoes substantial changes from infancy through adulthood. Neonates can discriminate between collections that differ by a 3 to 1 ratio, a ratio of 3 to 2 at 9 months of age, and up to a ratio of 11 to 10 in adulthood (Halberda and Feigenson 2008). The ANS may also support numerical intuitions related to arithmetical concepts and procedures. By 2 years of age, ANS representations are believed to support an intuitive understanding of ordinal relations of object sets (four objects > three objects > two objects) and possibly an implicit understanding of the effects of adding one object to or subtracting one from collections of a small (<4) number of objects.

In recent years, the neural signatures of these quantitative abilities have been studied in infants and young children (e.g., Ansari 2016), revealing both similarities to and differences from the brain systems that are engaged when adults process quantities. As with adults (and nonhuman primates), the engagement of the IPS and prefrontal regions is prominent during infants’ and young children’s processing of quantitative information, but with a strong right hemispheric bias, as contrasted with bilateral engagement in adults. Hyde et al. (2010), for instance, used near-infrared spectroscopy to identify the brain regions that are engaged when 6-month-olds discriminate between collections of objects (e.g., four vs. eight). They found increased activity in the right parietal lobe, localized in an area consistent with the adult IPS. Other studies suggest that the engagement of the IPS in both the left and right hemispheres of adults is due to their expertise with symbolic mathematics; that is, the engagement of the left IPS during the processing of quantities

associated with number symbols may only emerge with formal schooling.

On the basis of the numerical and potentially arithmetical competencies built into the ANS, it has been hypothesized that this system may be the foundation for children's learning of symbolic mathematics. Indeed, early studies found evidence that individual differences in ANS acuity were correlated with individual differences in children's mathematical achievement generally and perhaps to learning disabilities in mathematics. The results from subsequent studies have been more mixed, and there is now considerable debate regarding when during learning and how strongly ANS acuity contributes to symbolic mathematics. The primary alternative hypothesis is that young children's general mathematical achievement may be more strongly related to the speed and accuracy with which they can compare or manipulate (e.g., order) the magnitudes associated with Arabic numerals than to performance on measures of ANS acuity; in other words, the foundation for formal mathematical development may be children's learning of number symbols (number words and Arabic numerals) and the quantities they represent.

A recent meta-analysis found stronger associations between measures of number symbol processing (e.g., speed of determining which of two numerals is larger) and formal mathematical competencies (e.g., performance on achievement tests) ($r \sim 0.30$) than between measures of ANS acuity and these competencies ($r \sim 0.24$) (Schneider et al. 2016); the correlation between measures of ANS acuity and formal mathematical competencies is attenuated ($r \sim 0.16$) but still significant after controlling for domain general abilities, such as intelligence. One possibility is that fluency in processing number symbols and non-symbolic quantities independently contributes to different aspects of formal mathematical competencies. Another possibility is that ANS acuity has a time- and content-limited influence on the early learning of symbolic mathematics. Indeed, a series of studies revealed that the relation between measures of ANS acuity and young children's

mathematical achievement was fully mediated by their understanding of the cardinal value of number words, controlling for domain general cognitive abilities, preliteracy skills, and parental education (e.g., Chu et al. 2015). In this view, ANS acuity facilitates children's learning of the meaning of number words and Arabic numerals, but does not directly contribute to their formal mathematical development thereafter.

This cannot be the entire story, however; that is, it is not simply a mapping of number words or numerals to ANS representations. In nonhuman species, the development of mappings between the numerals (e.g., "3") and the quantities they represent (e.g., "●●●") takes thousands of trials to achieve, but once young children learn the first few ANS-number symbol mappings, they make a critical conceptual leap. They understand that all count words or numerals have a unique quantity associated with them and can infer these quantities once they learn the standard sequence of symbols (e.g., "one, two, three, ..."). Although the ANS embodies quantity information, nonhuman species do not make this conceptual jump. The ability to make these types of explicit, generalizable conceptual insights may be uniquely human, but exactly how this ability interacts with the ANS is not currently known.

Conclusion

Studies that span myriad species all point to the existence of an evolved system for representing and comparing the approximate quantities of discrete collections of objects and continuous quantities (e.g., area) and perhaps providing an intuitive understanding of aspects of arithmetic. In primates, magnitude representations are situated in the intraparietal sulcus and are co-activated with areas of the prefrontal cortex during quantity discriminations. Although much is now understood about the behavioral and brain signatures of this evolved system, its relation to competence with formal, symbolic mathematics is vigorously debated and not fully understood.

Definition

A key trade-off that organisms face concerning quantity versus quality in offspring: organisms that tend to invest heavily in offspring also tend to have lower numbers of offspring whereas organisms that invest little in offspring also tend to have higher numbers of lower quality offspring.

Introduction

Organisms continually face trade-offs for how to allocate limited energy and resources. One of the key trade-offs involves the quantity versus the quality of offspring. On the one hand, if organisms invest heavily in their offspring to better their developmental and survival outcomes, they tend to only have enough resources to produce a small number of “high-quality” offspring. On the other hand, if organisms make little parental investment per child, they can produce a large number of “low-quality” offspring – although each child has a lower chance of survival, there is a higher probability that at least some offspring will survive long enough to reproduce.

Ecological Conditions Affecting Reproductive Trade-Offs

According to life history theory (e.g., Stearns 1992), which concerns the allocation trade-offs

that organisms face throughout their lifespans between somatic investment (maintenance and growth) and reproductive expenditures, different species as well as organisms within species tend to evolve a reproductive strategy that favors quantity or quality based on various ecological conditions. As described below, such ecological conditions can be broadly classified into two types: environmental harshness and environmental unpredictability.

Environmental Harshness

A key factor that affects reproductive trade-offs is environmental harshness. Environmental harshness is indicated by the rates at which external factors result in the death or disability of organisms at each age in a population. External causes of disability and death, or extrinsic morbidity-mortality (Ellis et al. 2009), include predation, droughts, and disease and can occur regardless of organisms' allocation of resources between the competing life functions of maintenance, growth, and reproduction. When adults face high extrinsic morbidity-mortality (e.g., homicide, famines), offspring quantity is favored over quality. That is, if the environment imposes high rates of unavoidable mortality, an adult organism would benefit by quickly producing a larger number of offspring to increase the probability that some will survive into adulthood long enough to reproduce and propagate their genes. Heavily investing in a small number of high-quality offspring may not pay off in an environment with high risk of adult mortality, due to the higher likelihood of disability and death of the parent before the offspring receive the full benefits of their investment. For example, among the Ache, homicide, external warfare, and accidental deaths associated with food acquisition are some of the leading causes of death among adults. In turn, mating partnerships among the Ache are relatively short and women have children by several different fathers, reflecting a preference for offspring quantity over quality (Kruger and Nesse 2006). In contrast, when extrinsic morbidity-mortality affects the young, offspring quality is favored over quantity. An example of juvenile extrinsic morbidity-mortality can be found among red deer,

where male juveniles have high mortality rates as a result of their greater susceptibility to food shortages due to their faster growth rates and greater nutritional requirements (Clutton-Brock et al. 1985). In this case, adult red deers are better off investing more parental care into a small number of offspring to better ensure their survival in the face of environmental harshness rather than to produce a large number of offspring who are all unlikely to survive without sufficient parental investment. However, a high-investment strategy is only valid when parental investment has an effect on offspring survival. In contexts where offspring survival rates are independent of parental investment, offspring quantity would be favored over quality.

The effects of environmental harshness on the trade-off between quantity and quality of offspring also depend on population density (Pianka 1970), resource availability, and predation. For example, research on Trinidadian guppies has shown that environmental conditions such as high extrinsic morbidity-mortality (due to high predation) and high resource availability favored offspring quantity over quality. Although the costs of mortality are high and unavoidable in harsh environments, the strategy of producing a large number of offspring can only be sustained if there are enough resources in the environment for these offspring. In contrast, environmental conditions such as low predation, high population density, and lower resource availability favor offspring quality over quantity. High competition for resources as a result of high population density and limited resources leads to greater investment in offspring growth in order for offspring to be more competitive in such environments. Indeed, guppies in such environments invest more heavily in a small number of high-quality offspring to improve their chances of survival in a highly competitive environment.

Environmental Unpredictability

Environmental unpredictability refers to variation in environmental harshness over time and space (Ellis et al. 2009). Many organisms live in environments where resources and mortality rates vary in unpredictable ways due to factors such

as the behavior of predators or the weather. In unpredictable environments, morbidity-mortality risks are largely insensitive to the adaptive decisions and strategies of organisms and, therefore, are unavoidable. When there is high variation in adult mortality, adults are better off producing a large quantity of offspring rather than heavily investing in a small number of high-quality offspring due to their susceptibility to changing mortality rates.

However, when there is high variation in juvenile mortality, organisms may engage in one of two types of bet hedging: conservative and diversified (Einum and Fleming 2004). Conservative bet hedging corresponds to favoring offspring quality over quantity. In species where harsh environmental conditions affect an entire population over generations (e.g., years of drought), it is more beneficial to produce a small number of high-quality offspring who are equipped to handle the fluctuating conditions of the environment rather than a large number of low-quality offspring who are all unlikely to survive. In contrast, diversified bet hedging corresponds to favoring offspring quantity over quality. In species where environments vary substantially across individuals and within single generations, a large number of offspring (who have high phenotypic variance) would be preferred to increase the probability that at least some offspring would have a phenotype that would allow them to survive long enough in their environmental conditions to reproduce and propagate their genes.

Offspring Quality Versus Quantity Preferences in Humans

Human environments generally consist of low extrinsic morbidity-mortality (due to low predation pressures as a result of humans being at the top of the food chain), high population densities due to low extrinsic morbidity-mortality and efficient hunting-gathering practices, and high levels of competition for limited resources. These environmental conditions have resulted in humans evolving a general preference for offspring quality over offspring quantity. Low levels of extrinsic morbidity-mortality allow parental investment to have positive effects on offspring's

health, competitiveness, and reproduction; hence, it pays off for humans to invest heavily in their offspring to ensure their effectiveness in the highly competitive environment. In particular, it is adaptive in such environments for human males to produce only a few offspring, typically with the same mate, and to invest heavily in those offspring to ensure that they are of higher quality. As such, human paternal investment in children as well as monogamous marriage may reflect adaptive responses to morbidity, population density, and resource competition. Despite the fact that humans as a species are on the slow end of the life history continuum, however, there are key within-species differences in humans as a result of different environmental conditions.

Humans may evolve to favor either offspring quality or quantity depending on cues to extrinsic morbidity-mortality. When there are cues in the environment that extrinsic morbidity-mortality levels are high, humans tend to favor offspring quantity over quality. In these environments, heavy parental investment in offspring would not shield them from the dangers in the environment and would not enhance their fitness. Hence, parents would be better off producing a large number of offspring instead. One of the most important cues of extrinsic morbidity-mortality is low socioeconomic status (SES). Indeed, research has found that there is a negative correlation between SES and offspring number (Vining 1986) and a positive correlation between SES and levels of parental investment per child (Ellis et al. 1999). This could be because people living in low SES environments are more exposed to disability and death (thus cueing them to the harshness of their environment), but at the same time, they possess adequate resources to support the growth and reproduction of a large number of offspring.

Other important cues to extrinsic morbidity-mortality levels are personal knowledge of deaths among adolescents, exposure to violence, and environments characterized by short life expectancies. These cues inform individuals about their own and their offspring's probability of survival (which is likely to be relatively low) in their environment, thus causing them to favor offspring quantity over quality so that at least some of their offspring can survive. Harsh and

neglectful parenting styles can also indicate to offspring that a parent favors offspring quantity over quality, which signals to offspring that this is the appropriate strategy for their environment, thus propagating this strategy in future generations (Berezkei and Csanaky 2001).

Cues to the level of unpredictability in the environment are also informative. Interestingly, it is the level of unpredictability in the environment experienced during childhood that shapes preferences for offspring quantity versus quality. For instance, one indicator of childhood unpredictability is the number of parental changes as a result of divorce, death, remarriage, and adoption, among others. Frequent changes in parental figures indicate a high level of environmental instability and predict earlier age at first sexual intercourse, higher rates of premarital intercourse, teenage pregnancy, and premarital birth, which may all indicate a preference for offspring quantity over quality. Another indicator of childhood unpredictability is the frequency of residential change. Children who frequently move experience changes in social groups and may be more likely to join delinquent groups, who are more accepting of newcomers. Joining these delinquent groups may expose them to harsher environmental conditions which may prompt them to favor offspring quantity over quality. Indeed, frequent residential mobility is associated with earlier age at first sexual intercourse, multiple sex partners, and higher rates of premarital sex and pregnancy.

Conclusion

The application of life history theory to explain the reproductive behavior of organisms has been fruitful and has the potential to guide further research regarding the evolution and development of specific phenotypic traits and strategies associated with the trade-off between offspring quality and quantity. Understanding this important trade-off may provide insights into how organisms make reproductive decisions in not only the environments where they evolved but also in the modern world. In such evolutionarily novel contexts, offspring quality is so highly favored by humans

that the populations of many wealthy, industrialized societies – including all of Asia and parts of Europe – have been shrinking in recent decades. Researchers and policymakers who have been concerned with population growth rates and aging populations would benefit from a consideration of life history theory and, more generally, evolutionary biological perspectives.

Definition

A measure of the probability that two individuals share a gene due to recent, common ancestry.

Introduction

Relatedness is a consequence of individuals sharing copies of particular genes or alleles. Alleles are variants of the same gene, for example, one of the genes for eye color has an allele for blue eye color and an allele for brown eye color. The coefficient of relatedness, denoted by the symbol r , is a measure of the probability that two individuals

share the same allele via a recent, common ancestor, and thus it is “identical by descent” (Hamilton 1964). This measure excludes any identical alleles that are shared simply by being members of the same population or species.

Calculating the Coefficient of Relatedness: r

In diploid species like humans, and most other mammals, an egg and sperm, each containing half the normal number of chromosomes, fuse to form a single cell or zygote; therefore, each parent contributes 50 % of its genes. Half of a child’s genes come from their mother, and the other half of their genes come from their father, which means that the probability that the child shares an allele, identical by descent, with its mother is $1/2 = 0.5$ and with its father is also $1/2 = 0.5$.

R can be calculated for any pairs of relatives, for example, a grandparent and grandchild are related by one fourth. One parent received half its genes from the grandparent and then passed on half of these genes to their child. With distant relatives this becomes more difficult to follow, but there’s a simple method that can be used to calculate r , and it starts with the drawing of a family tree or pedigree (Fig. 1).

At each generation link (indicated by the arrows), 50 % of a parent’s genes are passed on, so there is a 0.5 probability that a particular allele

R = Coefficient of Relatedness, Fig. 1 Family tree. Letters refer to individuals, and the direction of an arrow indicates a parent-to-child relationship

is passed on. For n links, the probability is $(0.5)^n$. Thus to calculate r between any two individuals, we need to identify the shortest possible pathways or number of links between them, via any common ancestors. For direct relationships, this is straightforward. For example, A and D are parent and child with one link, so $r = (0.5)^1 = 0.5$; A and H are grandparent and grandchild with two links, so $r = (0.5)^2 = 0.25$.

D and F are full siblings with the same parents, and so to calculate r the links are counted via both parents (from D to A to F and also from D to B to F) so $r = (0.5)^2 + (0.5)^2 = 0.5$. H and I are also siblings, but with only one parent in common they are half-siblings, so $r = (0.5)^2 = 0.25$. H and J are cousins with two common ancestors, their grandparents, A and B. Thus $r = (0.5)^4 + (0.5)^4 = 0.125$. These calculations assume that incestuous inbreeding, which would increase the value of r , has not occurred within the family tree (Fig. 1).

Conclusion

The relatedness coefficient, denoted by r , is a measure of the likelihood that two individuals share a copy of the same allele, via a recent common ancestor (Hamilton 1964). It can be calculated for two individuals using a known pedigree or family tree, by identifying the common ancestors and counting the number of generational links between them.

Definition

Race encoding is a by-product of adaptive cognitive mechanisms to solve socialization and coalitional problems. Thus, phenotype and other traits work as a social badge for racial identification.

Introduction

Choosing a social interaction is an adaptive problem that would have favored cognitive mechanisms designed to make good decisions about socialization and group engagement (Kurzban and Leary 2001; Kurzban and Neuberg 2005; Kurzban et al. 2015). Just as there are evolutionary mechanisms prepared to associate fear with nonhuman predators, similar mechanisms exist to facilitate the association of fear with coalitional outgroup members (Cosmides et al. 2003). Such psychological mechanisms that enable individuals to distinguish quickly and efficiently between in-group and out-group are necessary to promote avoidance and caution with respect to out-group members. After eliciting these associations, they can be triggered immediately on the perception of out-groups.

Several characteristics are used by humans as clues or social badges to distinguish allies and rivals (e.g., dress, behavior, or language) (Cosmides et al. 2003). Among these, phenotypic traits (i.e., skin color, face shape, hair texture) that evoke the idea of race can be used to determine this categorization (Kurzban et al. 2001). Racial identification does not necessarily imply racism, it is just one way of categorizing people in groups. But racism requires such identification of people as being in or out of racial group. Thus, there is an important computational mechanism, since racial stereotypes are derived from this racial identification. And many of the discriminations and prejudices against minority groups stem from stereotypes.

Race Perception and Encoding: A Badge for Social Categorization

It seems very likely that natural selection has favored the development of a machinery encoding

sex and age automatically and mandatorily, but the same did not occur for race (Cosmides et al. 2003; Kurzban et al. 2001; Voorspoels et al. 2014). The reason is that no specific psychological mechanism was selected in the course of evolution for race encoding, since hardly our ancestors moved for great distances. Thus, it is unlikely that a mechanism for the identification of races has developed, since the individuals had no contact with populations of distinct phenotypic traits. In addition, our ancestors usually lived with individuals of different ages and sex, but not of other races. Therefore, selected cognitive adaptations for sex and age encoding allowed useful inferences, while there would be no reasons for a specific mechanism in relation to race.

In this regard, in social psychology prevails the perspective that people encode race automatically and mandatorily of all individuals. In an evolutionary perspective, categorizing individuals by race is not inevitable, but it occurs as a by-product of the adaptive mechanism for coalitions and alliances (Cosmides et al. 2003; Kurzban et al. 2001). Thus, phenotypic traits would be considered by the cognitive mechanisms for the in-group and out-group processes. Race would be a social badge of differences between groups arising from the alliance-building machinery. That is, there is no exclusive mechanism for race encoding. These operations are performed via nonautomatic or mandatory computational processes (Cosmides et al. 2003).

When individuals are categorized as in-group or out-group, there are many internal and external aspects that crosscut race, and it is possible for individuals to adopt one of these characteristics for group classifications rather than race. In addition, any clues (such as phenotypic characteristics) should only be significant insofar as they acquire predictive validity for the existence of a coalition. Indeed, people seem to have experiences that involve race in their lives, and that predict patterns of cooperation and conflict.

A research conducted by Kurzban et al. (2001) showed that an exposure of approximately 4 min to an alternative world weakened the tendency of racial categorization. This suggests that racism is maintained because of other systems of social

alliance and it can be eradicated. Moreover, when badges of coalition affiliation do not track race, subjects reduce the degree to which they categorize people by race, and may even stop to do so. Once the cognitive apparatus detects the relationship between apparent badges and loyalty, these can emerge in the cognitive system as reliable clues of an alliance (e.g., dress, language, posture). In this way, humans detect these shared clues – which may be the race – and infer social alliances. Thus, race would be one of the variables that indicates coalitions, but other alliance social badges can be used.

This identification, as well as other social clues, can precipitate the categorization “us versus they.” Social badges can be used as a criteria to discriminate in favor of the in-group and against groups considered to be rivals. This process immediately evokes negative perceptions, as well as hostile feelings and attitudes toward rivals (e.g., aversion, unfavorable opinion, denial of access to resources) (Cosmides et al. 2003). Such anticipation impedes cooperation and creates a predisposition for competitive interaction between groups.

Conclusion

Human relations of cooperation and competition between individuals and groups can be explained by many adaptive cognitive mechanisms selected during the evolution of the human species (Kurzban and Leary 2001; Kurzban and Neuberg 2005; Kurzban et al. 2015). The human cognitive architecture contains many functionally specialized computational systems, but race encoding is a by-product of coalitional psychology, not an independent system. In fact, coalition allegiance is what the mind is encoding when we identify race (Cosmides et al. 2003; Kurzban et al. 2001; Voorspoels et al. 2014). Researches highlight the dynamic nature of social categorization that indicate race is a badge for alliances and coalition, and other arbitrary clues can be linked with this process. Thus, contextual changes in the badges that indicate inclusion or exclusion of groups may mitigate racial encoding. If contextual

information can reduce racial stereotypes, this can help the development of new strategies to reduce racial prejudice and discrimination (Williams et al. 2016).

Introduction

Evolutionary psychology proposes the evolution of psychological mechanisms as part of the evolution of an organism, pointing out which contexts activate these mechanisms and the behaviors resulting from them; thus, the result of an evolved

psychological mechanism is related to the solution of a specific adaptive problem (Buss 2015). In this sense, many of these problems were solved by the natural selection of mechanisms that made social behavior possible (Neuberg and Schaller 2016). For example, living in communities facilitated protection against predators, nurturing of offspring, and maintenance of resources. Nevertheless, the proximity with others also had downsides. The possibility of nonreciprocal collaboration and mating competition, which in some cases would lead to violent and, sometimes lethal, encounters rank as relevant problematic issues in these contexts. Because of that, for this social living to work, some threat detection mechanisms had to evolve. This included the capability of recognizing members of the in-group and to respond to cues of possible harmful behavior of members of out-groups (Neuberg and Schaller 2016).

Social Categorization and Discrimination

Kinzler et al. (2010) point out the social categorization is a trait that is displayed early in the childhood, and despite having infinite arbitrary criteria for labeling later in life, some categories are especially influent in early life, namely, age, gender, and race. Child, by the age of 2–3, is already capable of distinguishing people and treating them differently based on sex, and by 4–5, they already can distinguish people by race. This mechanism of social categorization is believed to be naturally selected, once it appears consistently among humans in different contexts and cultures (Kinzler et al. 2010).

Through this categorization, one could perceive other people's characteristics similar to his own and recognize his in-group. Similar individuals are normally taken as in-group, even if they do not share a good portion of one's genes. This distinction is known to imply in cooperation and support in front of those perceived as in-group belonging (Efferson et al. 2008).

In the other hand, people tend to less cooperative and often defensive and/or aggressive to

out-group members (those that are not perceived as similar or related). That's because, historically, out-groups implied harm on contact, usually due to territorial and resource disputes. However, social categorization is not sufficient to support avoidance and hostility with out-group members; a cognitive association between some kind of specific negative emotional state, for example, fear or anger, or specific stereotypes and the out-groups should be present to promote behavioral avoidance and caution (Schaller and Neuberg 2008).

Schaller and Neuberg (2008) pointed out that some features are naturally conceived as cues of aggressive disposition. Angry face expressions, for example, tend to evoke avoidance or defensive responses. This type of stimuli is normally more prominently perceived in out-group members, and once one has been in harmful dispute with a member of an out-group, the whole group can be taken as a threat. Thus, it indicates that people may learn to associate danger stereotypes and fear with coalitional out-group members (Schaller and Neuberg 2008).

Notably, this threat detection system has evolved to be highly sensible, considering that danger imposed by a possible failure in this process. This fact, however, implies in the possibility of associating threat to harmless expressions or behaviors, which means that for defensive behavior to be triggered, threat doesn't have to be real, but some condition may have been linked somehow to an actual threat, making people perceive aggressive cues where there are none (Becker et al. 2010; Neuberg and Schaller 2016).

Moreover, it is known that the context largely influences these perceptions. Resource scarcity and harsh mating disputes or even environmental conditions could lead to misperceptions of cues of possible threats. In general, people who perceive themselves as in danger conditions tend to be more aggressive to out-groups (Neuberg and Schaller 2014). Throughout history, it is possible to observe that prejudice in general tends to be greater when social tensions arise, as it will be discussed later. Considering this, the concept of threat may have a central role in the understanding of contemporary prejudices. In fact, different

types of threats elicit different types of behavioral and emotional responses: escape, anger, and disgust, which implies different discriminatory responses.

In summary, racism consists in a discriminatory response that emerges from a process of social categorization, which groups all Black people within a same uniform group and associates them with depreciative stereotypes.

Evolution and Modern-Day Racism

In a sense, acts of behavioral discrimination, stereotypes, and contemporary prejudices can be viewed as results of psychological adaptations from natural selection mechanisms for managing threats and opportunities (Neuberg and Schaller 2016). Nevertheless, as already mentioned, the mere "us-them" distinction is not enough to elicit aggressive responses, especially in modern-day societies.

Besides the social categorization, the association of negative stereotypes is key to the expression of any kind of prejudice, including racism. These stereotypes, in turn, are culturally constructed and are directly influenced by political, economic, and social contexts. So, despite depending on a psychological mechanism that was selected by the environment in human evolutionary history, racial prejudice is also reliant on variables existing in human present environment.

Jackson Jr. (2016) defends that racism, at least as we know it today, has not emerged until the eighteenth century. The prejudice based on race bias, in this sense, could have emerged at a context in which White people, who had economic power and social privileges in hands, starts understanding Black and Latino people as out-groups. This would, by itself, favor discrimination. In addition, though, negative stereotypes are attributed to those groups. These people are seen as subservient, less-than-human kind, which culturally served the purpose of social dominance. That, in a context of scarcity and social instability, could significantly influence race discriminative behavior.

Conclusion

In sum, mechanisms of social categorization developed from an early age are important to understand racial prejudice; however, in addition to simple categorization, it is necessary to enhance the preponderant role of identifying out-group members as potential threats to the safety of in-group members, giving them negative stereotypes. These perceptions, although biased, are adaptive, since they induce aggressive or avoidant responses that facilitates the protection of the members of the same group and their offspring (Gilead and Liberman 2014), consequently increasing the individual's fitness.

It should be emphasized that the activation of threat management mechanisms does not necessarily require the out-group express, for example, aggressive cues, which may indicate that stereotypes are attributed arbitrarily and used to base the subjugation of a group by the other, justifying discriminatory behavior. In this sense, the cultural, social, economic, and political contexts are fundamental to understand the implications of modern-day racism in human's evolutionary history.

Finally, it is pointed out that evolutionary psychology does not manifest an attempt to naturalize any kind of prejudice but only to comprehend and systematize the possible mechanisms involved in discriminatory acts.

Definition

Discrimination elicited by negative stereotypes that highlights race/ethnicity as a social badge of threat and reduces subjects to a set of negative

characteristics, feelings, and behaviors associated with their race/ethnicity.

Introduction

Many contemporary social problems are related to processes of discrimination that lead to exclusion and conflicts. Human psychological processes emerged as adaptations to environmental pressures throughout evolution and so evolved sensitive psychological mechanisms that promote avoidance and caution in regard to out-group members (Kurzban and Leary 2001; Neuberg and Schaller 2016). In social psychology, the perspective that people automatically recognize and take into account someone's race is dominant (e.g., Devine 1989). From an evolutionary perspective, categorizing individuals by race is a by-product of the adaptive mechanism for coalitions and alliances and is not inevitable (e.g., Cosmides et al. 2003; Kurzban et al. 2001; Voorspoels et al. 2014).

Social Categorization and Prejudice

Throughout evolutionary history, humans have lived as hunter-gatherers in relatively small subsistence groups. Cognitive mechanisms designed to enhance socialization arose by natural selection in order to solve the adaptive problem of social interaction (Kurzban and Leary 2001; Kurzban et al. 2015). Group life in forage societies provided important advantages, such as facilitating mate or parental investment, protecting against predators, and assisting the achievement of mutual goals (Kurzban and Neuberg 2005). However, some threats may also emerge, such as competition for resources and sexual partners, disagreement that could culminate in physical aggression or death, exploitation of generosity without reciprocity (i.e., low-effort free riders), and contamination by infectious diseases (Kurzban and Neuberg 2005).

For survival reasons, it was necessary to develop a machinery sensitive to the social badges or behaviors that signalize threats. The perception

of threat clues automatically activates aversive cognitions and emotions (Cosmides et al. 2003; Kurzban and Leary 2001), such as feeling angry about low-effort free riders and disgusted about the ill aspects in sick people (Kurzban and Neuberg 2005). Thus, each specific threat is associated with a singular set of emotional, cognitive, and behavioral responses (i.e., prejudice syndrome, Schaller and Neuberg 2008). These psychological adaptations designed to reduce these threats include, for example, the tendency to stigmatize in-group members who violate social norms and to avoid those who are contaminated by infectious diseases (Kurzban and Neuberg 2005).

Race Encoding and Racial Identification

Many mechanisms regulate intergroup relations. Social categorization involves a complex set of computational separate systems designed for different types of sociality. For example, the encoding of age, gender, and coalitional in-group or out-group is an automatic process (Kurzban et al. 2001). Natural selection appears to have favored the development of a human cognitive machinery for sex and age encoding, but the same did not occur for race (Cosmides et al. 2003; Kurzban et al. 2001; Voorspoels et al. 2014). Our ancestors usually lived with individuals of different ages and sex, so that selected cognitive adaptations for sex and age encoding allowed useful inferences. In contrast, our ancestors hardly moved for great distances, so it is unlikely that they had contact with populations of distinct races. Therefore, it is likely that no specific psychological mechanism was developed in the course of evolution for race encoding and this process is thus a by-product of the adaptive mechanism for coalitions and alliances.

Several characteristics are used by humans as social badges to distinguish allies and rivals (e.g., clothing, behavior, or language; Cosmides et al. 2003). Among these, phenotypic traits (i.e., skin color, face shape, hair texture) that evoke the idea of race can be used to determine this categorization (Kurzban et al. 2001). Racial

identification does not necessarily imply racism, as it is just one way of categorizing people in groups, but racism requires such identification of others as being an in-group or an out-group member. It is thus an important computational mechanism, since racial stereotypes are derived from this racial identification and many of the discriminations and prejudices against minority groups stem from stereotypes.

Racial Discrimination

Categorizing an individual as an out-group member is not sufficient to promote belligerence. A cognitive association linking the out-group and its members to some sort of negative stereotype may provoke fear and avoidance, as the out-group members may be regarded as threatening and dangerous through a stereotyping process. Although it may elicit a discriminatory process, it is speculated that in some situations, emotional states such as fear might have promoted greater fitness advantages, as real threatening stimuli might have been avoided (Schaller and Neuberg 2008).

This threat detection system has evolved to be highly sensitive, and, consequently, a sense of threat is commonly elicited even in the presence of harmless social behaviors or badges (Neuberg and Schaller 2016). Therefore, avoidance is triggered regardless of whether the threat is real or not; it is only necessary that a stimulus is perceived as a real threat. This perception is influenced by contextual factors that may make individuals even more prone to aggressive reactions to non-real threats (e.g., resource scarcity, high mate competition; Neuberg and Schaller 2016), which is why prejudice might emerge strongly among intense social tensions. The perception of danger, insecurity, or fear might generate a more prejudiced, self-centered, and aggressive attitude so that people tend to associate aversive (cognitive and physiological) responses to out-group faces more quickly (e.g., Navarrete et al. 2012). Indeed, individuals tend to automatically perceive out-group members as sources of potential danger on account of these prejudice-

triggering cognitions (see, e.g., Neuberg and Schaller 2016).

Prejudice can be defined as an individual form of avoidance or a negative feeling linked to a social badge; racism can be described as prejudice aimed at individuals from racial minorities, notably black people (Cosmides et al. 2003; Kurzban et al. 2015; Neuberg and Schaller 2016). A set of negative stereotypes (i.e., racial prejudice at the institutional, structural, social level) link the subjects to degrading characteristics stereotypically associated with their race. Racism elicits discrimination by stereotypes that highlights race as a social badge of threat so that the subject racially identified is perceived as someone with a predisposition/disposition to emit/be characterized by negative characteristics, feelings, and behaviors (Schaller and Neuberg 2008).

We categorize people by race, even if biologically it does not exist. In fact, we use several characteristics as an alliance clue. However, how does this association occur between the traits that evoke race encoding and the subsequent association with danger? (And why does it not signal alliance?). This probably occurs because historical social processes maintain this negative association (Kurzban et al. 2001). Race is simply one historically contingent subtype of coalition. If other social badges were presented simultaneously to race markers, they would overlap with it (Kurzban et al. 2001; Voorspoels et al. 2014), and race could be a social badge of differences between groups arising from the alliance-building machinery, reducing its threat-triggering potential. As this process occurs mainly through the in-group/out-group categorization process, some contextual aspects that crosscut race could be used to modify the negative valence associated with it and thus reduce its avoidance-eliciting potential and, consequently, reduce racism. For example, Kurzban et al. (2001) have shown that a 4-minute exposure to an alternative world has weakened or stopped the trend of racial categorization. This suggests that racism is maintained because of other systems of social alliance and can be eradicated. So, racism, understood as the process of discrimination against different races elicited by prejudice syndrome (i.e., a suite of

thoughts, emotional responses, and behavioral inclinations designed to deal with a particular perceived threat), can be mitigated by the interruption, for example, of racial encoding (see Schaller and Neuberg 2008). An intervention that seeks to reduce racism could also target some other part of the process that leads to discrimination, namely, racial identification arising from race encoding, prejudice arising from stigmatization, and, finally, discrimination. Interventions could also address other badges that may signalize a threat, such as low socioeconomic status, poor access to resources, and diseases.

Negative stereotypes that elicit prejudice and, subsequently, racial discrimination must have emerged in a scenario where social power and privilege should be under the control of one group (such as white people) who have begun to harass another group (such as black people). That is, stereotypes are culturally constructed and influenced by political and socioeconomic contexts. In this sense, Moore (2012) argues that between 6000 and 12,000 years ago, when leukodermic (paler skinned) populations arose, racism would have arisen because of the conflicts and hostility generated by phenotypic differences between leukodermic and melanodermic (darker skinned) populations. This process has strengthened over time. For example, in more recent periods as in Greco-Roman antiquity, there was already proto-racism (i.e., attitudes and actions analogous to racism, but that predate the modern concept of race), as group-based slavery began between the seventh and ninth centuries among the Arabs.

Conclusion

Human relations of cooperation or exclusion can be explained by cognitive machinery selected in evolutionary human history. Human cognitive architecture consists of a set of separate systems designed to solve adaptive problems associated with sociality, which requires a dynamic performance in the management of these systems. Therefore, such processes are flexible and responsive to immediate contextual characteristics.

Understanding racial prejudice requires a comprehensive analysis. The computational processes that regulate social categorization involve several mechanisms to address threats, and each set of emotional responses, cognitions, and behavioral inclinations was designed to deal with a specific threat (i.e., prejudice syndrome; Schaller and Neuberg 2008). Some groups are victim of multiple forms of prejudice syndrome because they are perceived as multiple forms of threat. This is triggered by badges that signal threat, regardless of whether this threat is real or not. Negative stereotypes are then arbitrarily assigned and serve as a justification for discrimination, being thus important to address the socially constructed aspects of discrimination as illustrated by the fact that racism was established by the political, socioeconomic, and cultural domination of white people. Racism is therefore maintained because of other systems of social alliance, and it can be eradicated.

The evolutionary approach allows new ways of addressing the problem of prejudice. Because different racial beliefs can be generated by multiple inferential mechanisms, only research that links them can generate precise explanations. This ends up impacting the elaboration of interventions, since each prejudice syndrome must be separately addressed. As different prejudices can be linked to different mechanisms, this will require multiple strategies. Other potential implications for interventions include, for example, the possibility to act in processes prior to the elicitation of negative stereotypes, such as in race encoding through aspects that crosscut race or contextual changes that diminish the propensity of evoking prejudice (e.g., promote feelings of security and safety).

Definition

Randy Thornhill is an entomologist and evolutionary biologist at the University of New Mexico, especially noted for his applications of evolutionary biology and evolutionary psychology to human behavioral science. He attained fame beyond the academy for work with Craig Palmer on applying biological knowledge to the phenomenon of human rape (Thornhill and Palmer 2001). Although the book was specifically intended to help inform law enforcement in the identification and capture of criminals, and the prevention of crime, this was not deemed sufficient justification by many (Dreger 2016). However, Thornhill is more famous within the academy for work on insect mating, parasite-stress theory, and sociosexuality.

Introduction

Thornhill's early work (like that of sex researcher Alfred Kinsey) was in entomology (his MSc was in this discipline), and this may well be no

coincidence. Studying insects allows for a degree of detachment from issues of human sentimentality and political commitment (Thornhill and Alcock 1983) focusing on the underlying nuts and bolts of the key drivers of mating success (or failure) rather than human rationalizations of same.

Thornhill brought this same detachment to the study of politics. Here a major insight was that the surface (proximate) rationalizations of political loves and hates may have underlying (ultimate) mechanisms driven by the need to associate with some and disassociate with others. Thus, the parasite-stress theory was born (Thornhill and Fincher 2014). Human immune systems are remarkably complex and, increasingly, being seen as drivers of human behavior in their own right. Thornhill was an early predictor of such mechanisms, realizing that traits such as religiosity, personality, and political leanings were non-accidentally linked to local adaptations to parasite loads). These traits are, in effect, part of the behavioral immune system.

Open vs Closed: Opportunities or Threats?

Thornhill has managed to link a number of behaviors, for example, to do with physical and moral disgust, attitudes toward strangers, and even food. For example, in the same way that regions of high temperatures tend toward spicy foods (because spices have antimicrobial properties), Thornhill hypothesized that visible signs of immunocompetence (such as low fluctuating asymmetry) may also be preferred in such regions. Fluctuating asymmetry is a marker that seems to hold across taxa as a visible honest advert of developmental stability and thus heritable resistance to parasites – making one an attractive partner. There also appear to be local and predictable responses to pathogens. Data from the Global Infectious Diseases and Epidemiology Network did indeed confirm that cultural groups that split along the collectivist-individualist axis showed a high covariance of collectivist (and thus xenophobic) attitudes and high pathogen stress. This work has

the interesting implication that the goal of making cultures more liberal would be best advanced through health care rather than argument – a conclusion that Thornhill appears happy to endorse.

Humans are obligate investors. Human babies are highly demanding in terms of both time spent in the womb and the aftercare required for them to be viable. Demands fall disproportionately on the females in our species – their minimum parental investment is considerably higher than the male minimum potential parental investment. What this means is that a suite of mating options are available to both sexes, but these are constrained in important ways.

Sociosexuality is a dimensional trait – which might also be appropriately termed an orientation. At one end of the dimension is restricted sociosexuality – characterized by an insistence on commitment in advance of engaging in sexual interactions. At this end of the scale, a typical person would answer positively to questions such as “I require a feeling of emotional closeness before engaging in sexual intercourse.” At the other end of the dimension is unrestricted sociosexuality – characterized by a willingness to engage in sex without commitment. Those at this end of the scale typically answer positively to questions asking whether they would be willing to have multiple sexual partners concurrently or to questions such as “sex without love is perfectly permissible between consenting partners.”

Within the general framework of life history theory, which models differential economic allocations of resources to key adaptive traits, sociosexuality describes a set of proximate markers of behaviors relating to mating and parenting effort. Organisms maximize their fitness by focusing resources on where they will have the most effect but, like an effective investment portfolio, bets are often hedged in various ways to achieve this fitness maximization. While both sexes benefit in similar ways from long-term mateships (e.g., through sharing resources and having reliable partnerships), there are predicted to be some sex differences in terms of what constitutes short-term mating opportunities – of which a major component is sociosexuality. This is what scholars have indeed found.

Given the obligate investiture of human females, it is predicted that willingness to engage in short-term matings will, for women, be mediated by said short-term partner's genetic quality. For example, Gangestad and Thornhill (1998) found that willingness to engage in short-term matings (especially extra-pair copulations) was highest when women were at the most fertile part of their cycle. Furthermore their preferences shifted, at these times, toward males who were more symmetrical.

It is likely that at least part of the measured sex differences in sociosexuality are mediated by testosterone. The relationship here is a complex one. In the trade-off between allocating resources to mating and parenting, testosterone facilitates mating effort. Men in long-term mateships tend to have lowered testosterone. McIntyre et al. (2006) used the sociosexuality index (SOI) focused on extra-pair interests to find support for the prediction that the relationship between testosterone and sexual partnership status would rest on extra-pair sexual interests.

Like all evolutionary scholars, Thornhill has had to contend with what appears to be a very human cognitive glitch that refuses to see evolutionary explanations as enhancing existing proximate ones rather than replacing them.

Critics who wish to emphasize that sex differences arise from local social structure (Eagly and Wood 2005) claim that the concept of patriarchy explains said differences. Patriarchy is a (proximate) descriptor of a cluster of local behaviors and dispositions rather than an ultimate explanation of the factors leading to fitness maximization; thus criticisms of this kind tend to miss the point of evolutionary explanations. For a behavior to be socially constructed, it must have pieces to be constructed from. An explanation like "patriarchy" is thus no explanation at all – it is merely a description which hangs in the air without visible means of support.

Indeed there is little evidence that critics are even aware of the logical distinction between proximate and ultimate explanations, relying instead on a folk-science understanding of "biological" as meaning "fixed action pattern" or similar. Evolutionary explanations are not

alternatives to proximate ones – they enlarge and compliment them. Therefore to the extent that "patriarchy" can be taken to be a meaningful designator (and this is not always clear), it should be the case that ultimate explanations will match with it. This is indeed what we find. For any meaningful cultural descriptor of "patriarchal" (meaning traditional male dominated official marriage systems), cross-cultural measures of the SOI match the predictions of evolutionary theory.

For example, when controlling for local markers of mating threats and opportunities that can be assumed to have occurred and re-occurred over evolved time, SOI measures track fitness maximization. Overall women are far more varied in their SOI than men are (mean $ds = 0.74$; Lippa 2009) and more variant in their sex drive across cultures (mean female to male variance ratio = 1.64, which also implies that SOI and sex drive are not identical).

Conclusion

Randy Thornhill still continues to publish widely and with a multitude of coauthors. If there has been any effect of a vocal (but one hopes minority) public unwilling to see their traits as having biological elements, then this has not had a visible effect on his investigations (Thornhill and Gangestad 2015).

Definition

The use of force or threat to achieve penile-vaginal sex without consent.

Introduction

Rape is more commonly defined as penile-vaginal penetration of a female without her consent by force or threat (McKibbin et al. [2008b](#)). However, definitions of rape vary, and rape laws have been reformed around the world leading to more broadened legal definitions. The main changes are related to the victim's gender, victim resistance, and the definition of consent (Tracy et al. [2013](#)).

Although legal standards regarding victim resistance have been excluded in most places, there are still stereotyped rape views that require visible marks of resistance (Tracy et al. [2013](#)). These stereotyped views consider, for example, that rape is only perpetrated by strange and violent men in an isolated street (Burt [1980](#)). In reality, estimates suggest that about 40% of reported rapes in the United States are committed by an acquaintance man and over 50% are perpetrated by an intimate partner (Black et al. [2011](#)).

Rapes are also often underreported, mainly due to its many negative consequences for the victims (McKibbin et al. [2008b](#)). These can include physical and psychological impacts, such as sexually transmitted infections, feelings of shame and fear, and the development of psychological disorders

(Chaudhury et al. 2017). In addition, Perilloux et al. (2012) identified social and mating-related costs, such as damage to a woman's sexual reputation and decreased self-perceived mate value. Rape also impacts female reproductive success, and, therefore, could be an adaptive problem to ancestral women.

Rape Costs

Research on rape has shown that forced sexual intercourse can be observed in many species including insects, birds, reptiles, and primates. For instance, some male animals presented anatomical features designed to facilitate forced copulation (e.g., scorpionflies; McKibbin et al. 2008b). Small males' orangutans presented reproductively disadvantaged compared to large males because they are considered less attractive for females. Thereat, they are likely to resort to rape more often (Malamuth et al. 2005). These pieces of evidence indicate that rape has been a recurrent adaptive problem for other species.

From an evolutionary approach, rape represents a circumvention of female choice (McKibbin et al. 2008b). In fact, rape can result in an unwanted pregnancy by a man she has not chosen and whose genes and resources are unknown (Buss 2015). In addition, human rape creates other risks for a woman's reproductive success. A raped women risks being blamed, being abandoned by her partner, and having their reputation and desirability affected. Therefore, women have evolved anti-rape mechanisms (Buss 2015).

This strategy has also possible costs for men. A man who raped a woman can face parental retaliation and woman's resistance which can result in physical injuries and even death (Apostolou 2013). Given these high costs, for rape to continuous occurring in the context of human evolution, the benefits must have outweighed the costs (McKibbin et al. 2008a). Conflicts between men and women regarding parental investment and mating strategies could contribute and increase the likelihood of male engagement in sexual coercion (Malamuth et al. 2005).

Theories of Rape

It is controversial if men have evolved specialized psychological mechanisms to rape, or if it is a byproduct of mechanisms selected to solve other adaptive problems (McKibbin et al. 2008a). These issues create two competing evolutionary perspectives: rape-as-adaptation theory and by-product theory of rape. The rape-as-adaptation theory assumes that rape has been selected as a useful behavior to male reproduction success and is the product of specialized psychological adaptations (Archer and Vaughan 2001). Human males do not present any anatomical feature designed to facilitate forced intercourse. However, if rape were an adaptive strategy, an ancestral man who raped must have gain reproductive advantages over a man who did not (McKibbin et al. 2008a). One hypothesis is that men of low mate value (i.e., a man with low status and few resources) are unlikely to be chosen by females; therefore, they might get reproductive benefits in using a forced-sex mating (Thornhill and Thornhill 1983). Rape allowed men to circumvent parental and female choice (Apostolou 2013) and enables them to access females of high mate value (Thornhill and Thornhill 1983). This hypothesis has been questioned mostly because evidence showed that rape is not restricted to men of low mate value and sexually coercive men have reported a greater number of sexual experiences than expected (Lalumière et al. 1996).

Rape-as-adaptation theory lists some supposed specialized mechanisms related to rape. For example, an ability to assess the vulnerability of potential victims, an increased sperm count in rape ejaculations compared to consensual sex ejaculations and a preference for fertile rape victims (Malamuth et al. 2005). These mechanisms have been used as supporting evidence of this hypothesis.

In addition, there are circumstances where rape holds minimum costs and could be adaptive. War-time is the most recurrent example, but other situations, such as when the victim is unprotected, when there are very few chances of the men being recognized or discovered, and when a victim is unlikely to disclose the rape, also indicate opportunities where the costs of following forced-sex mating are low (Apostolou 2013).

In contrast, the by-product theory does not admit that rape is a previously selected behavior. It suggests that rape derived from other evolved mechanisms, such as the desire for sexual variety, the willingness to engage in casual sex, and the general use of psychical aggression (Symons 1979). Men typically present some sexual proclivities, such as being more eager to copulate, being less selective about their sexual partner, and looking for a greater number of partners, and the combination of all these sexual proclivities may lead to rape (Vandermassen 2011). Therefore, this approach endorses that rape itself is not an adaptive feature and it is maintained indirectly due to other adaptive behaviors (Archer and Vaughan 2001).

Although these are the two main evolutionary hypotheses regarding rape, there are other hypotheses involving attempts to explain rape. Shields and Shields (1983) proposed that rape represents a conditional strategy, in other words, rape is only adaptive under certain conditions. They endorse that most males are capable of raping depending on the situation and that rape is not a behavior restricted to males of low status (Archer and Vaughan 2001). In this sense, McKibbin et al. (2008a) proposed five types of rapists, namely: (1) disadvantaged men who resort to rape, (2) men who are sexually aroused by violent sex, (3) men who rape opportunistically, (4) high-mating-effort rapist, and (5) partner-rapists motivated by assessments of increased risk of sperm competition. The first type refers to a mate deprivation hypothesis, which assumes that one motivation to men for rape is the absence of consensual sex opportunities. However, most researches have not found evidence to corroborate this type of rapist. An alternative motivation that has been pointed is a perceived relative deprivation, which refers to individual's expectations about their sex experience (Malamuth et al. 2005).

The second type indicated that some rapists possess different psychological profiles and can be considered "specialized" rapists. This type may be sexually aroused by violent sexual situations and may evaluate greater attractiveness to rape victims rather than consensual female partners.

Such men could also lack the inhibitory factors of sexual arousal to force that other men possess (Malamuth et al. 2005).

The next hypothesized type is the opportunistic rapist, a man that might shift for sexual coercion in low-costs circumstances. For example, a rape strategy can be used by some men in situations that a victim has high vulnerability and the risk of retaliation is low. The fourth type describes a man with dominant and psychopathic traits who pursue a great number of sexual partners with minimal investments, therefore, is more likely to engage in sexually coercive behaviors.

Finally, the last type includes men who commit partner rape in response to the risk of sperm competition (McKibbin et al. 2008a). In the animal world, forced-in pair copulation is rare, because typically there are not long-term pair bonds in most species. However, evidence that supports this hypothesized type is that men with unfaithful partners were more likely to perform sexual behaviors versus men with no suspect of partner's infidelities (Goetz and Shackelford 2006). That result indicated that sexual coercion may be a method to avoid cuckoldry. Although some data is consistent with this typology of rapists, future research should continue to investigate possible individual differences in men who committed rape as well as specific circumstances related to rape.

Conclusion

Nowadays, it is not clear if rape is the result of an adaptation mechanism favored by evolution selection or if it is a by-product of other adaptive behaviors. There are also unanswered questions regarding rapist's types and motivations. It is important to highlight that these evolutionary approaches do not justify sexual coercive behaviors and by no means promote rape. Therefore, evolutionary explanations do not imply that rape is inevitable. Men may have psychological mechanisms related to rape but that does mean that they cannot control their sexual desire or are not responsible for their behavior. Humans can control their tendency to eat fatty food, hints they also

can control any evolved mechanisms towards rape (McKibbin et al. 2008a).

In fact, an evolutionary perspective provides insights into why men rape, what are the costs and benefits of rape, and why rape is being maintained over human evolution. Finally, this evolutionary framework can set grounds for developing programs to reduce sexual violence (McKibbin 2014).

Definition

Date rape is a subset of acquaintance rape; it is nonconsensual sex, defined as vaginal, oral, or anal penetration, through the use of force or threat of force, committed by someone with whom the victim has gone on a date.

Introduction

This chapter is a review of the research done on rape and dating from an evolutionary perspective. By no means does this review justify rape, rather it is meant to review the current research in the aforementioned field.

In this review, we will begin with a brief discussion on the premise of evolutionary psychology by examining sexual selection, gender roles, and aggressive behavior. The primary interest is to look into the reasons why male adolescents engage in date rape. Through reviewing the research on date rape in adolescents, we will examine data found in dating behaviors, patterns of violence, and sexual strategies of adolescents. The review will continue in describing the impact of status, and appreciating its relation to survival and reproductive success, both during our evolutionary past and in our present lives. Finally, this review will explain how adolescents may use date rape to climb the social hierarchy through attaining status via dominance.

Natural Selection, Sexual Selection, and the Ancestral Environment

Through an evolutionary lens, we are able to understand the underlying workings of the human mind and behaviors in the environmental context they were adaptive in (Buss 1995; Tooby and Cosmides 1990). The psychological mechanisms that work the human mind today are ones that were built in ancestral environments, at a time when certain behaviors addressed recurrent environmental pressures. Exploring the psychological mechanisms through this lens, researchers have been able to contextualize the human mind and behavior in the ancestral environment they were formed in (for a review, see Tooby and Cosmides 1990).

One specific challenge that our ancestors faced in regards to reproduction and one that we currently see today are the natural forces of sexual selection; men and women have different reproductive costs when it comes to mating. The cost for men to mate is the time spent having sex, while the cost for women is 9 months of pregnancy, health, and childbirth.

The structure of our past environment made survival and reproduction highly competitive due to social dynamics in such environments. As an accepted member of a group, one reaped the benefits of food, protection, and access to women (for a review, see Hagen 2008). In our ancestral past, groups were highly exclusive; if an individual was deemed unfit, their membership in the pack was highly detrimental to the group's survival.

The pressures from exclusivity of group-membership forced outsider ancestral men to find a different way to mate, one which would allow them to gain reproductive success despite their possible shortcomings in physical attractiveness, status, and resources. This brings the possibility that ancestral men not belonging to any group, and facing high exclusivity in group membership, may have used rape as a method for sexual access and passing on their genes.

Aggressive Behavior, Narcissism, and Social Hierarchy

Through an evolutionary perspective, Thornhill and Palmer (2000) argue that men who lack resources and status, rape in order to pass on their genes; however, there is little evidence to support this claim. In a similar argument and framework as evolutionary psychology, other researchers have argued that narcissistic men (similar to men who lack resources) share the aggressive responding attribute with rapists (Baumeister et al. 2002). Evolutionary metatheory has found that common attributes among males who commit rape, include being aggressive, more eager to mate, more sexually assertive, and less discriminating to choose a mate (Thornhill and Palmer 2000).

Laboratory findings have confirmed that distress and sexually aggressive behavior is more likely in narcissists who have received criticism, insults, and who have felt their pride threatened. Based on the narcissistic reactance theory, a narcissistic male's entitlement to sex by his partner roots from attempts to increase self-esteem through peer admiration and validation. Seeking peer validation has great importance to narcissists; therefore, obtaining sex, by any means necessary, is believed to give the narcissist peer validation for having sex that will help him maintain status among his peers (for a review, see Baumeister et al. 2002).

Date-Rape and Adolescents

In the majority of rapes that occur, the victim knows the perpetrator (Pedersen 1992). Young women are more likely to be raped by an acquaintance or a romantic partner than by a stranger. Adolescents and young adult women are four times more likely to be raped than women in any other groups (for a review, see Rickert and Wiemann 1998).

A large percentage of reported sexual offenses are committed by adolescents (Fehrenback et al.

1986). Adolescents are particularly vulnerable to being victims and perpetrators of date rape because of their young age and inexperience (Vicary et al. 1995). There are multiple risk factors that are linked to adolescents committing date rape. This is similar to how in our ancestral past a male who has been alienated from his group is more likely to engage in sexual assault. Furthermore, male college students who display high levels of hostile masculinity and engage in impersonal sex are at an increased risk for committing sexual assault (Wheeler et al. 2002).

One of the most prominent risk factors that is involved in adolescent date rape appears to be the use of alcohol (Rickert and Wiemann 1998; Muehlenhard and Linton 1987). Alcohol is closely linked with date rape as alcohol reduces men's restraints against committing violent behavior and offers an excuse for sexual assault, as well as reducing a woman's ability to withstand an assault (Muehlenhard and Linton 1987). It has also been seen that alcohol produces a boost in egotism in young men (for a review, see Baumeister 2002). Alcohol is also more likely to be involved in a case of date rape than a date where sexual assault did not occur (Muehlenhard and Linton 1987).

Conclusion

In the field of evolutionary psychology, researchers have examined the root of rape behavior through contextualizing rape in ancestral times and through examining the environment that the behavior may have been adaptive in. Environmental pressures are constantly changing; therefore, behaviors that may have been adaptive for our ancestors in previous environments are not adaptive in our current environment today (for a review, see Tooby and Cosmides 1990). Researchers propose that the purpose of investigating an issue such as rape through an evolutionary lens is invaluable as it provides a better understanding of where such behavior root from, with the ultimate goal of building new strategies

for preventing rape and implementing efficient antirape programs (McKibbin et al. 2008).

Definition

Traits or behaviors evolved to reduce the risks of women being raped.

Introduction

Rape has occurred over time and across cultures (Buss 2015). It is responsible for inflicting severe psychological, physical, and reproductive costs on victims (Boyd 2011; Perilloux et al. 2012). The impacts on physical health can involve clinical conditions, sexually transmitted infections (Chaudhury et al. 2017), self-harm (Chen et al. 2010), and to a lesser extent even death (McKibbin 2014). The psychological effects can range from feelings of fear, shame, and anxiety to the development of psychological disorders (Tsai et al. 2016). Particularly in women, sexual violence can lead to gynecological complications and unwanted pregnancy (Krug et al. 2002).

In general, rape is a crime perpetrated mostly by men against women. Therefore, women more frequently tend to use some resistance strategies for avoiding rape. These strategies can be physical actions (e.g., scratching, hitting their attackers) or verbal resistance such as screaming, yelling, and pleading. In addition, women also tend to engage in rape prevention behaviors, for example, avoid wearing revealing clothing and going out alone at night (Ullman 2007). From an evolutionary perspective, women may have evolved psychological

mechanisms that motivate such rape avoidance behaviors (McKibbin et al. 2011).

Rape results in many negative consequences for women, including costs on reproductive success. A woman who has been raped risks: (a) being abandoned by her partner, (b) reducing their desirability to future mate, (c) losing offspring investment by the genetic father, and (d) an unwanted pregnancy with a sexual partner she had not chosen (McKibbin and Shackelford 2011). A forced-sex mating strategy could increase fitness by enabling men to circumvent parental and female choice (Apostolou 2013). Mate choice is a central step of women sexual strategies because it is what guarantees good genetic quality and the availability of protection and resources to their offspring (Buss 2015). Therefore, the greatest cost inflicted by rape on women may be the circumvention of their mate choice, since this can jeopardize their reproductive success (McKibbin et al. 2009).

Women are the sex that presents greater obligatory parental investment associated with pregnancy and lactation, and so they tend to be more selective of their sexual partners (Buss 2015). This fact constrains the amount of offspring a woman can successfully produce. In the rape context, women can entail high parental effort in an unwanted child with a man of unknown genetic quality and few resources. Considering these costs associated with rape, a strong selection pressure over evolutionary history may result in psychological mechanisms that motivate women behaviors toward avoid being raped by men (McKibbin et al. 2011).

Rape Avoidance Mechanisms

Rape has affected female reproductive success, representing a recurrent adaptive problem over human evolutionary history. Then, women may present evolved psychological mechanisms designed to motivate behaviors to avoid men's sexual coercion and rape. So far, it is not clear to evolutionary psychology if these behaviors reflect specialized evolved adaptations or by-products of more general mechanisms (Ellsworth and Palmer

2011). Despite that, several studies provide evidence suggesting the existence of specialized psychological mechanisms that motivate women to assess the risk of being raped or to evaluate the risk of a man being sexually coercive (McKibbin et al. 2009). For example, Gangestad et al. (2007) showed that women during the fertile phase tend to rate men as more sexually coercive. It can indicate that due to the greater risks of conception, women may be more attentive to signs of male sexual coerciveness, which might serve as a mechanism to prevent rape.

Several studies have cited some hypothetical strategies, such as the formation of alliances with other males and females to get protection from a rape threat (Smuts 1992), and the sensation of fear in face of risky situations of being raped (Chavanne and Gallup 1998). In addition, according to Wilson and Mesnick (1997), women's preference for physically and social dominant mates can reflect an anti-rape adaptation, because such partners would be more likely to defend them from a possible rapist. This notion is known as the bodyguard hypothesis. Another hypothetical mechanism is the psychological pain experienced by women after being raped. Thornhill and Thornhill (1990) argued that psychological pain works as an alert to the circumstances in which the rape occurred, leading women to avoid such circumstances and, thus, preventing revictimization. The authors found that reproductive-aged women (vs. post-reproductive-aged women) experience greater psychological pain after being raped, which may be because the former have a greater risk of pregnancy from rape.

Measuring Rape Avoidance Behavior

From an evolutionary perspective, it seems coherent that women have evolved mechanisms that motivate rape avoidance behaviors. However, there was still a need for an instrument that could capture the main behaviors emitted by women for preventing sexual assault. McKibbin et al. (2009) have addressed this gap by proposing the Rape Avoidance Inventory (RAI), a reliable

and valid measure composed of 69 behaviors. All the items were developed based on the reports of women about specific behaviors they had already performed or would perform in order to avoid being raped. Using an act nomination procedure, initially, McKibbin et al. (2009) collected 83 specific behaviors that formed the preliminary version of the scale. From this initial set, 14 items did not meet the validity and precision criteria and were excluded from the final version.

The final version is composed by 69 items related to four components: Avoid Strange Men, Avoid Appearing Sexually Receptive, Avoid Being Alone, and Awareness of Surroundings/Defensive Preparedness (McKibbin et al. 2009). The first component consists of behaviors with the purpose of avoiding unfamiliar men or those who represent a greater risk of being sexually coercive (e.g., Avoid taking rides with men I don't know). The Avoid Appearing Sexually Receptive component comprehends behaviors related to woman's clothes or appearance. For example, women tend to "avoid wearing revealing clothes" or "avoid attracting attention" as a way to reduce their physical attractiveness to a potential rapist. This component also includes behaviors that may diminish perceived sexual receptiveness (e.g., Avoid making out with a man I have just met). The Avoid Being Alone component includes behaviors to keep around others (e.g., "Avoid walking alone at night"). Finally, the Awareness of Surroundings/Defensive Preparedness encompasses behaviors that function to maintain a woman alert to possible signs and situations of danger (e.g., Look around before I get out of my car) and behaviors that can increase woman's ability to defend herself against a threat of rape (e.g., Carry a knife) (McKibbin et al. 2009, 2011).

The four components of the Rape Avoidance Inventory (RAI) conceptually converges to four guidelines for female defense against rape introduced by Judson (2002), which are: "avoid group of idle males," "do not attract attention," "do not leave home alone," and "do carry weapons." This may be evidence for the construct validity of RAI. The negative correlation between the performance of rape avoidance behavior and women's interest in and the pursuit of short-term sex found by

McKibbin et al. (2009) represents additional evidence of the validity of the RAI.

One possible limitation of this measure is that the majority of items are related to stranger rape over acquaintance rape, despite the greater numbers of the latter. However, it must be considered that the RAI was developed from women's report about their behaviors, and that, in general, women are more fearful of rape by an unknown person, which may indicate that stranger rape was the greater adaptive problem faced by ancestral women (McKibbin et al. 2008). The RAI contributed to the advancement of the research on individual differences related to rape avoidance behaviors.

Individual Differences in Rape Avoidance

Considering individual features and context variables involved in rape, individual differences of women rape avoidance behaviors that were evolutionarily selected become more evident as an adaptive mechanism for different environmental pressures. Evolutionary psychologists have been studying the existence of individual differences in rape avoidance behaviors in women (McKibbin and Shackelford 2011); therefore, evidence suggests that rape avoidance behaviors could vary when some women's individual variables are accountable (e.g., attractiveness, relationship status, kin living close by, and the age of the possible victim).

Theoretically, over evolutionary history, women that responded with rape avoidance behaviors to situations with rape-related risk could have shown more reproductive success (McKibbin and Shackelford 2011). However, evidence suggests that some individual traits could influence some women to be more targeted than others in rape-related situations. McKibbin and Shackelford (2011) gathered evidence that demonstrated that rape avoidance behavior is positively correlated to women's attractiveness, involvement in a relationship with a romantic partner, and the number of kin living close-by. However, despite previous

hypotheses, the age of women did not correlate negatively with rape avoidance behaviors as expected by the authors.

Although the mere presence of the described traits does not incur in a causal relation with rape avoidance behaviors, in an evolutionary perspective it is coherent that women with those characteristics were more targeted by would-be rapists or could be more harmed by the costs of a rape. For example, attractive women are the ideal standard in the men's preference to mate, once it is a feature related to immunocompetency, fertility, and an honest indicator of good genes, thus, more likely to generate healthy offspring (Buss 2015). Hence, those women would be more targeted by men for mating proposes. However, men with low mate value generally are not chosen by attractive women, turning rape as a coercive and successful copulation strategy to those men. Thus, attractive women would be more inclined to perform rape avoidance behaviors (McKibbin 2014).

In addition, women that are involved in a romantic relationship have reported more rape avoidance behaviors (McKibbin and Shackelford 2011). Evidence suggests that having a romantic partner is significantly and positively correlated to avoid appearing sexually receptive and being alone, intending to minimize the possibility of being courted by other men and, consequently, of being raped (McKibbin 2014). Also, significantly related to behaviors that aimed to avoid appearing sexually receptive, to maintain awareness of surroundings and to being defensively prepared were observed when the woman reported having male or female family members living nearby (McKibbin and Shackelford 2011). Having kin living in proximity could minimize eventual risk-related contexts (e.g., walking home alone at night; McKibbin 2014). Protection to family members is an inclusive fitness management provider, once protect a family female from rape, would be indirectly be protecting the family genetic fitness, and hence when the female has the possibility to select her preferable mate, her offspring have a higher chance of survival and parental support (McKibbin 2014; McKibbin and Shackelford 2011).

Conclusion

In sum, due to environmental pressures that humans were submitted in evolutionary history, rape became a sexual strategy that increased the pressure to female counter-adaptation to it, the rape avoidance behaviors. Due to physical, psychological, and evolutionary costs of being raped, behaviors that could minimize the possibility of being a victim of this crime were a constant necessity for women.

From the evolutionary perspective, it is possible to comprehend how these behaviors were selected in early human history. However, the transformation of society's laws has influenced more severe punishment to perpetrators of this crime but has not yet extinguished this harmful male behavior.

Despite the evolutionary explanation for counter-adaptations that are helpful to decrease risky contexts to rape, it is relevant to highlight that this is not a justification and do not intend to legitimize victim's blaming arguments. This crime is a product of coercive mating strategies. Modern society has a long way to go to extinguish coercive copulation and to rape avoidance behaviors not be a necessity to women worldwide anymore.

Sexual aggression committed against women by outgroup men during times of intergroup conflict.

Introduction

Intergroup conflict is a ubiquitous feature of both modern and tribal human societies. In these conflicts, women are unlikely to be involved as warriors or members of raiding parties and are also less likely to be the deadly targets of warfare. Rather, women are the “resource” for which men are competing and consequently suffer as the victims of sexual aggression at the hands of the attacking group. We review the literature linking rape and warfare and present an evolutionary perspective positing that men’s propensity to engage in warfare serves as the function of increasing reproductive success through various mechanisms, of which the rape and capture of outgroup women is one.

Evolutionary Background

Males and females differ in the minimum level of investment that is required to produce viable offspring (Bateman 1948; Trivers 1972). The obligatory investment of males ends after ejaculation, but females bear the costs of a long gestational period and (among hunter-gatherers) up to 4 years of lactation. Even after weaning, women continue to play the role of the primary caregiver (Lancaster and Lancaster 1983).

For males, large investments in parenting are potentially risky given that males do not have paternal certainty. Furthermore, the relatively minimal paternal investment that is required to produce offspring means that males benefit to a greater extent than do females from large investments in mating. Consistent with this theorizing is evidence suggesting that early humans were mildly polygynous (Mitani et al. 1996; Symons 1979). In such a system, females are a limiting resource to men’s reproductive fitness, thereby creating an incentive for males to compete with other males for access to resources that will increase their ability to acquire mating opportunities. In this competition, some men will perform well and others will perform poorly, leading to larger variability in male’s reproductive outcomes than females (Andersson 1994).

Intrasexual competition among males for mating access occurs via multiple routes. Competition may include contests for territorial resources that provide the best protection from predators or access to nutrients, as well as more intangible resources such as social status, that can be converted into reproductive opportunities. This conversion occurs either because there is a direct appeal of the acquired resource to females or because the resource increases success in competition with rival males. Competition for such resources can occur among men within a group, as well as between groups in the context of warfare, when men form coalitions to usurp territory, resources, and mates from rival groups. It is this intergroup warfare that is the focus of this entry.

Reproductive Advantages in Warfare

Although there are risks involved in warfare, the potential benefits are to be accrued if victorious are substantial. Expansion of territory, acquisition of resources, increased social status as a warrior, and the rape and capture of the outgroup’s women all contribute to men’s mating success, indirectly or directly. Below, we focus on the direct reproductive benefits of warfare, in particular, reviewing evidence of the link between warfare and rape. The chaotic nature of conflict provides many affordances for sexual coercion to be used against women, especially by men of the invading group. These include the absence of consenting heterosexual mating options, antagonistic attitudes toward the victims’ group, and a reduced likelihood of punishment following acts of sexual violation (Smuts 1996). As a result, rape is a common feature of intergroup conflict. Below, we first review accounts of wartime rape among modern hunter-gatherers and tribal societies in order to provide insight into the probably patterns of behavior of our evolutionary ancestors. We then review modern warfare and the patterns of sexual aggression that continue to persist.

Rape in the context of tribal and nonstate warfare. Women are rarely involved in warfare as warriors or members of raiding parties and are less likely to be the deadly targets of warfare.

However, women often suffer as the victims of sexual aggression at the hands of the invading group. Indeed, the stated motivation for many intergroup conflicts is explicitly related to mating goals. In traditional lowland South American societies, jealousy over women and the desire to gain captive women are two of the top three motivations for intergroup killings (Walker and Bailey 2013). Along similar lines, Sanday (1981) examined correlates of rape frequency in 75 tribal societies. The research found that rape frequency across societies was predicted by the frequency with which the society raided other groups with an explicit purpose to take outgroup women for wives ($r = 0.29$) and was also predicted by whether the society could be characterized as engaging in frequent warfare ($r = 0.21$).

It is clear from many anthropological accounts that outgroup men are the targets of lethal intergroup violence. In contrast, the lives of outgroup women are typically preserved in intergroup conflict, but they instead suffer as the victims of sexual aggression. Meggitt (1962) describes the raiding, and counter-raiding, between the Walbiri and Warramunga of the Central Australian Desert; “Walbiri war parties would then invade the Warramunga country in retaliation. If they were able to surprise the enemy camps and kill or drive off the men, they carried away any women they found” (p. 38). Similarly, describing the fighting of the Kurnai tribe in Southern Australia, Fison and Howitt (1967) write that “they only speared the men, and perhaps some children. Whoever caught a women kept her himself” (p. 214). Based on the anthropological work of Chagnon (1988), Wrangham and Peterson (1996) describe the intergroup raids of the Yanomamö: “The stated object of a raid is to kill one or possibly two men and escape. If the raiders can do so without risking losses, however, they may abduct a woman from the enemy village. The abducted woman will be raped by all the raiders, taken to their village, raped by the remaining men in the village, and then given as a wife to one man. She can expect to spend the rest of her life with her new companions” (p. 67).

Synthesizing a large body of work examining nonstate warfare, Keeley writes:

It is extremely uncommon to find instances among nonstate groups of recognizing surrender or taking adult male prisoners. Adult males who fell into the hands of their enemies were usually immediately dispatched. . . . The capture of women was one of the spoils of victory – and occasionally one of the primary aims of warfare – for many tribal warriors. . . . In general, nonstate groups preserved the lives of captives only when some material benefit would accrue; this approach generally limited the persons spared to women and children. (1996, pp. 83–87)

Evidence that warfare and raids spared women can also be inferred on the basis of the sex composition of archaeological remains. For example, Kohler and Turner (2006) argue that the disproportionate absence of women and children in a burial population may indicate that a group had been attacked and the women and children taken captive and moved to a different location. Indeed, their own examination of the archaeological record from late pre-Hispanic northern US Southwest reveals a pattern suggestive of intergroup raiding for women.

Modern warfare and rape. The association between warfare and rape appears to be a constant force across time. Brownmiller (1975) reported that rape has been associated with religious wars dating back to the First Crusade. Sexual assault took place as knights and pilgrims made their way to Constantinople (Wilson 1969). Additional evidence suggests that wartime rape occurred in Medieval European warfare, including wars between the Ancient Greeks (reviewed in Gottschall 2004).

Moving forward in time and closer to present day, sexual assault in warfare was acknowledged by Brownmiller (1975) to have been committed by German troops in the First World War when proceeding through Belgium. Reviewing the historical record, Lalumière et al. (2005) conclude that “Mass rape has been perpetrated by American soldiers in Vietnam, Pakistani soldiers in Bengal, German soldiers on the Eastern front in the Second World War, [and] Soviet soldiers during the invasion of Germany. . .” (p. 25). In

some conflicts, the numbers of female victims number into the tens of thousands. During the Japanese occupation of the then capital of China, Nanking, historians have suggested that 20,000 women were raped (Chang 1998; Roland 1997). The Warburton Commission, established to investigate the treatment of Muslim women during the Bosnian War, estimated that between 10,000 and 60,000 Muslim women were raped (Buss 1998).

The prevalence of rape in the context of warfare is so pervasive that in 2008 the United Nations Security Council unanimously voted to pass a resolution that would classify acts of sexual violence as war crimes, crimes against humanity, and acts of genocide. The resolution was prompted by the fact that, during armed conflict, “women and girls are particularly targeted by the use of sexual violence” and that “such acts...in some situations have become systematic and widespread, reaching appalling levels of brutality” (UNSC Resolution 1820 2008, pp. 1–2).

Psychological Associations between Mating and Warring

A great deal of evidence suggests that rape of outgroup women is incredibly pervasive in the context of intergroup conflict and warfare. Underlying this behavior may be a strong psychological association between mating and warring. Crouthamel (2014) examined the inner life of German soldiers in the First World War through an analysis of archival documents including diaries, letters home, newspaper stories, and court records. Crouthamel draws many contrasts between what was expected of the male soldier and their actual behavior. The idea that male soldiers would dogmatically pursue their country’s military mission without interruption from base sexual drives was contradicted by a venereal disease crisis that spreads gonorrhea and syphilis to many thousands of soldiers.

Crouthamel also notes that many soldiers reported experiencing sexual arousal during

combat, as well as sexual dysfunction following their experiences in warfare. Indeed, Germany experienced a steep rise in sex crimes committed by soldiers on leave from the First World War, including sexual violence and rape of girls under 14. Moreover, reports from soldiers suggest that some males craved the sensation and arousal generated in warfare but found it difficult to achieve in postwar situations (Crouthamel 2014). This aligns with many PTSD veteran accounts documenting sexual dysfunction following participation in combat. For example, Cosgrove et al. (2002) reported that 85% of male veterans experienced erectile dysfunction.

Experimental work substantiates elements of Crouthamel’s historical analysis. Chang et al. (2011) sought to empirically demonstrate the association between mating and warring. In their research, participants were primed with either attractive or unattractive pictures of the opposite sex. Following this, the participants’ attitudes toward war-related behavior were examined. Results demonstrated that men (but not women) exposed to attractive women (but not unattractive) reported more positive attitudes toward war (but not more positive attitudes toward trade conflict). Similarly, men exposed to attractive women displayed faster visual processing of war scenes and faster lexical processing of war-related words (e.g., wars, fight) – even compared to other aggressive words unrelated to war. These findings are consistent with the idea that men’s motivation for warfare lies in the reproductive advantages it provides, or in the least, that for men mating and warring are tightly connected.

Conclusion

Though it is difficult to provide precise estimates of the frequency of rape during military and tribal conflicts, the weight of evidence suggests that, throughout human history, intergroup conflict has sharply increased a woman’s risk of becoming the victim of sexual aggression. The persistent and pervasive nature of this evidence implies that

there may be a deep psychological association for men between warfare and rape.

Rational Actors

Homo economicus

Definition

Economic model of individual decision-making formalized as utility maximization.

Introduction

The rational actor model is based on an individualist and consequentialist conception of optimal decision-making. The model posits that a rational actor will choose the course of action that maximizes expected individual net benefits. The formal framework of the rational actor model was developed in economics (Luce and Raiffa 1989; Ramsey 2016; Savage 1972; Von Neumann and Morgenstern 2007). Also known as *homo economicus*, the rational actor model became influential across the social and natural sciences – including evolutionary models of human and other animal behavior through game theoretic applications (Smith 1982).

Homo Economicus

The rational actor model is formally based on the axiomatic foundations of expected utility theory (Savage 1972; Von Neumann and Morgenstern 2007). This economic decision-making model gained wide scholarly use due to its powerful analytical capabilities derived from a small number of axioms – assumptions

viewed as self-evident. Most importantly, it is assumed that rational agents have pre-given (exogenous) preferences that are complete and transitive (Von Neumann and Morgenstern 2007).

Completeness means that the agent has a preference between any two possible alternative outcomes (A and B) such that either A is preferred to B, B is preferred to A, or A is seen as equally valuable as B. Transitivity means that, comparing any three alternative outcomes, if A is preferred to B and B is preferred to C, then A is preferred to C as well. The model predicts that the rational agent will implement the action that maximizes the highest possible difference expected between benefits earned from the outcome achieved and costs expended in achieving this outcome.

The term rationality in the model refers exclusively to the efficiency and consistency of decisions. On the one hand, the rational actor is motivated by the optimization goal of making the most use of available resources to achieve desired ends (Robbins 1932). On the other, efficiency requires that the rational actor behaves consistently in achieving these ends. In this sense, the model is focused on instrumental rationality in means-ends relationships and is therefore distinct from theories about procedural (Simon 1976) as well as substantive rationality (Sen 1977).

A common misperception of the model is that rational actors are necessarily selfish. Although it is a long-standing assumption in economics that individual behavior is governed exclusively by self-interest (Edgeworth 1881), the formal framework of the rational actor model does not make this assumption. Instead, the model implies that the substance of the goals that a hypothetical rational actor may pursue is independent of whether these goals are pursued in a consistent and efficient way. For example, a selfless altruist, a profit-driven executive, and a dangerous sociopath can in principle all be perfectly instrumentally rational in pursuing their individual goals. However, this formal flexibility of the model is also a methodological weakness since any behavior can be viewed as

rational as long as it is internally consistent and efficient.

Conclusion

Although the rational actor model has fundamentally shaped the behavioral sciences, it is increasingly seen as an inaccurate and inadequate description of human psychology and behavior (Sen 1977; see also entries on ► [“Bounded Rationality”](#) and ► [“Resource Scarcity”](#)). In particular, recent findings from economic and psychology experiments resulted in a long list of cognitive biases and heuristics in actual human decision-making that clearly contradict the assumptions underlying the rational actor model (e.g., Tversky et al. 1990). Nevertheless, the model continues to be widely used, but it remains particularly useful for studying when and how actual human behavior deviates from the normative benchmarks of optimal behavior.

Definition

The range of environments that one phenotype has adapted to as a result of a genotype. Individual organisms or features that represent one type or the other are referred to as *tokens*.

Introduction

Organisms that are capable of adapting to their environment and reproducing successfully are selected over others that fail to do so. Adaptability or *plasticity* of an organism's inherited features, from an evolutionary perspective, would grant opportunities for the organism to travel and live across more diverse environments to obtain

resources essential for survival and reproduction. Evolutionary scientists recognize these ideas as *reaction norms and tokens*, which are responsible for the genetic and physical outcomes for all life forms, including humans.

Distinguishing Genotype and Phenotype from Reaction Norms

Each and every living specimen can be classified into groups based from its heritable material. Deoxyribonucleic acid (*DNA*), the molecule of life, accounts as the heritable material for the vast majority of contemporary life forms. The genetic composition of an organism is defined as its *genotype* (Lewontin 2011). Every organism has a unique genotype that ultimately characterizes its every quality.

Phenotype is exclusively the physical and behavioral features resulting from the genotype. Physical shape, size, movement patterns, cognition, etc. of every organism are examples of its overall phenotype (Lewontin 2011). Hair and skin color, body limbs and their locations, biological sex, and all other physical human universals compose the human phenotype. Each physically expressed feature is a product of the genotype and the general environment that the feature evolved from.

The general range of phenotypes that result from a single genotype is the *reaction norm* (Barrett 2012). The gills of a fish are an inherited adaptation to breathe oxygen from water; fish could not live outside their aquatic environments due to this physical attribute. A marine mammal, such as dolphin, lives in the sea and breathes oxygen in air when it surfaces; a dolphin's reaction norm is, therefore, more plastic than a fish's.

An organism's reaction norm may also be described as the interaction of its genotype and its evolutionary environments (Flatt 2014). Using the same example above, evolutionary environments of fish were likely to be less diverse relative to the evolutionary environments of dolphins whose ancestors lived on land before returning to the ocean. The reaction norm or a genotype's phenotypic plasticity can provide useful

information about the organism's evolutionary history. Every adaptation is a response to the selective pressures that constitute the organism's environments in the form of genotypic and phenotypic expression (Schlichting and Pigliucci 1995).

Tokens

Genotypes and phenotypes are classes in which an organism can be identified with. A *token* is the specific organism or trait(s) of a genotype or phenotype (Lewontin 2011). Tokens, in a more general biological context, are occurrences or examples of genotypic or phenotypic elements (Tibayrenc 2011). The fins of a fish, a phenotypic trait, would be tokens of an organism that swims in aquatic environments. A dolphin's unique genotype may be a token of the *Delphinus* genus, as a human's unique genotype may be a token of the *Homo* genus.

Significance of Human Reaction Norms to Evolutionary Psychology

Relative to the speed of biological evolution, the speed of environmental evolution is too fast. The survival of any species largely depended on the adaptability of their genotype's phenotypic expression (Wong and Candolin 2014). While inconsistent environmental conditions and environments are inevitable, the genotypes that produce the more versatile adaptations are naturally selected over less versatile adaptations (Rand 2016). The vast majority of contemporary life forms did not evolve in an environment containing uniform or fixed conditions. Relative to merely all other species that have ever existed, prehistoric humans encountered distinctive environmental forces that ultimately designed the adaptability of modern humans (Wong and Candolin 2014).

Like other species, humans demonstrate flexibility in their evolved traits. Physical features are conventionally conceived as adaptations; however, mental features, too, are human adaptations.

The central nervous system of humans is perhaps the most complex system ever created by biological evolution. More traditional psychologies describe the human mind as the product of only experiences and learned qualities, which is referred to as *the blank slate*.

It can be argued that the most significant adaptation that enabled the humans to dominate the globe is their higher intelligence. How to construct hunting tools; weave clothing; hunt various animals; harvest edible vegetables and fruit; build fires; raise healthy young; live in forests, woods, deserts, and frigid climates; and communicate these valuable skills and merits to human offspring required a nervous system of tremendous prowess. The organism most adaptable to change is selected over all others; the human brain and mind may be the adaptation that has granted humans the most flexible reaction norm achieved by any species.

Today, evolutionary psychologists are in close proximity to study the ultimate adaptations that formulate human reaction norms. Psychological mechanisms that engender emotions and behaviors that facilitated human survival and reproductive endeavors are the foundations of evolutionary psychological theories and hypotheses. The seemingly universal sense of disgust engendered by the notion of committing incest, for example, is hypothesized to prevent humans from conceiving young of poorer genetic quality. Incest avoidance, along with many other behaviors, is considered by evolutionary psychologists to be an adaptation that ultimately contributes to the reaction norm of humans.

Conclusion

Evolutionary psychology and psychology are descendants of biology. Biological principles underlie many psychological ones, and *reaction norms and tokens* are no exception to this perspective. All living organisms, especially humans, possess biological reaction norms that circumscribe their genotypic and phenotypic qualities. Like organisms, tokens of genotypes and phenotypes are selected for and against

based on their host's ability to adapt to its array of environments. With the human brain reaffirmed as a product of the human genotype and human evolutionary environments, evolutionary psychology is granted the opportunity to parse *higher intelligence*, the ultimate adaptation.

Recalibration Theory of Anger

Definition

The recalibrational theory of anger explains how natural selection designed anger to bargain for better treatment and how this can explain the major features of anger.

Introduction

The claim that anger has evolved via natural selection is not hotly contested. After all, anger bares many of the hallmark features of an evolved adaptation: it is a complex system instantiated in localized neural tissue (Potegal and Spielberger 2010), it shows early ontogenetic development (components of the adaptation are visible at 7 months, Stenberg et al. 1983), and it demonstrates many cross-cultural universals in basic design (Alonso-Arbiol et al. 2011; Ekman 1973; Wallbot and Scherer 1986). Furthermore, some features of anger are known to develop without exposure to the information that would be required to learn them through more general purpose systems, e.g., congenitally blind children produce normal anger

facial expressions (Galati et al. 2003). And so modern researchers generally conclude that anger is – at least in part – designed by natural selection (Potegal and Spielberger 2010).

The recalibrational theory, however, is the first theory of anger that (i) posits the precise selection pressure that evolved anger (i.e., animal conflict theory), (ii) derives the basic computational structure of anger from that selection pressure, and (iii) begins to catalogue the features of anger, each with reference to its evolved function. This leads to several advantages that the recalibrational theory has over other psychological theories of anger: (i) the theory is derived from well-established and validated models of conflict in evolutionary biology, (ii) the theory not only describes features of anger but can explain causally how those features evolved and what function they serve, (iii) the theory can be used to predict and explain multiple aspects of anger (e.g., aggression, negotiation, arguments, facial and vocal changes), and (iv) the theory does not rely on circular concepts that are often used to smuggle organized complexity under the umbrella of descriptive theories (e.g., “disrespect,” “frustration,” “bad treatment”).

The recalibrational theory was derived from the basic models of animal conflict that are used to explain the aggressive, threatening, and bargaining behavior of nonhuman animals. A review of this literature demonstrates that human anger has a kinship with these behavior systems and makes precise the selection pressures that – according to the recalibrational theory – designed human anger.

The Evolutionary Biology of Animal Conflict

There are striking parallels between human anger and bargaining aggression in nonhuman animals. These similarities include (Sell 2011; Sell et al. 2009b, 2014; Tooby et al. 2008):

- (i) Its triggering conditions (e.g., conflicts of interest, challenges to status)
- (ii) Individual differences in thresholds for anger (e.g., those with more bargaining power demand more deference)

- (iii) Patterns of aggression that can be triggered (e.g., low-cost demonstrations of formidability that escalate when neither individual backs down)
- (iv) Terminating conditions, e.g., submission of one's opponent
- (v) The body posturing preceding aggression
- (vi) The predictable sex differences in proneness to bargain with aggression
- (vii) Bodily and energetic shifts during bargain that prepare the organism for aggression
- (viii) The neurolocality of the bargaining systems that show continuity across mammals

These similarities suggest that the bargaining systems of other animals and the human anger system were designed by similar selection pressures, specifically resource conflict or "conflicts of interest."

So how do biologists explain animal conflicts? In short, animals have conflicts of interest because many reproductive benefits (e.g., food, mates) can only be acquired at another's expense. Aggression, then, is a tool that evolved to disrupt the functional complexity of another, rendering them incapable of contesting the aggressor's use of the resource (Huntingford and Turner 1987). Because of the potency of this selection pressure, animals evolved complex adaptations for governing their aggressive and bargaining behavior.

For any given conflict, an animal must determine whether to contest a resource or cede it to the other animal. Natural selection can be expected to design animals to attempt to take resources when the reproductive benefits of the resource outweigh the costs of seizing it (Maynard Smith and Price 1973). The benefit of winning a bout of aggression will be largely determined by the reproductive benefit of receiving the resource, e.g., the hunger level of the animal eyeing a piece of meat. The costs of seizing a resource are largely determined by how much one's opponent values the resource and a ratio variable that indicates the reproductive consequences for the actor of disregarding their opponent's welfare (Nowak 2006; Tooby et al. 2008). For example, the reproductive consequences for taking food from a relative will depend on how hungry the actor is

(benefit to $X = Bx$), how hungry her relative is (cost to $Y = Cy$), and the degree of relatedness between them (r), i.e., Hamilton's rule: $Bx > r * Cy$. Similarly, the selection pressures acting on a potential combatant who must decide whether to fight an opponent for food will look mathematically similar. The actor must weigh the benefit of the resource to themselves (benefit to X), how hungry his opponent is (cost to Y), and the relative ability of the organisms to impose costs on each other through aggression (i.e., relative resource holding power, RHP; see Hammerstein and Parker 1982; Maynard Smith and Price 1973). Similar mathematics underlies the selection pressures inherent in reciprocal altruism and other routes to cooperation (Nowak 2006).

In sum, for any given conflict, an animal will need to assess information relevant to the selective dynamics inherent in that situation, usually including the value of the resource to the self and other, kinship, and often other variables such as relative fighting ability, cooperative history, and so on. Many of these cues will vary across conflicts, e.g., how hungry each animal is, the presence of vulnerable offspring, and the organism's current energetic state. These cues must be reassessed – or estimated – during every conflict. Other cues are relatively stable, such as fighting ability, size, life stage, sex, estimated degree of relatedness, and so on. Because it is costly to reassess all of these variables for each conflict (particularly fighting ability – the more accurate assessments of which may require potentially lethal aggression), animals have evolved the capacity to store representations that correspond to relative bargaining power and use them as baselines for future conflicts with those individuals (Huntingford and Turner 1987). These stored variables give rise to dominance hierarchies on the group level but are in fact the output of information stored in each individual brain. Furthermore, these representations of relative bargaining power are – in a sense – resources that can be fought over. And thus animals will engage in aggressive tests with no resource at stake, in order to both demonstrate their formidability to their opponent and to learn the fighting ability of a future opponent (Huntingford and Turner 1987).

Bluntly averaging across many exceptions and unique species adaptations, animals are designed to assess their conspecifics to determine if they are afforded the appropriate “status” consistent with their bargaining power and recalibrate those individuals that do not afford them the status they are entitled to. This recalibration takes the form of aggressive posturing, escalating into bouts of communicative aggression and finally actual potentially lethal aggression if the target does not submit. According to the recalibrational theory, human anger is phylogenetically related to these bargaining systems.

Function of Anger

If, as the recalibrational theory suggests, anger evolved to navigate conflicts of interest, then one needs to understand how humans represent conflicts of interest and what kinds of mental structures evolved to decide a conflict in order to understand how anger can manipulate those mental structures (e.g., just as adaptations for bodily adornment must be understood by reference to adaptations for the assessment of attractiveness). In short, if anger evolved to recalibrate status-setting machinery in the minds of one’s conspecifics, then one needs a theory of that status-setting machinery in order to explain how anger works.

How Do Humans Represent Conflicts of Interests?

Just as with many other animals, humans faced conflicts of interest. During these conflicts, the individual human had to decide whether to take a benefit at another’s expense. Such a situation can be called a **cost-benefit transaction**. Cost-benefit transactions can be classified according to the ratio of cost to benefit (i.e., relative valuation of the contested resource) that results from the imposition of the cost on agent X for the benefit of agent Y. For example, in Fig. 1, there are five instances of cost-benefit transactions that differentially affect the welfare of agents Y and X. The size of the circle indicates the cost-benefit ratio (i.e., value (Y)/value (X)); the extent to which Y

Recalibration Theory of Anger, Fig. 1 Welfare trade-off ratio as a threshold of cost-benefit transactions

values the resource more than X). Such examples could be:

1. Person Y borrows X’s car and crashes it to avoid getting a \$20 speeding ticket (small benefit for Y, large cost to X).
2. A commercial pilot (Y) makes X wait for 30 min so that he can finish his birthday cake.
3. Y takes the last doughnut at a meeting between X and Y (equal value to both).
4. Y ruins X’s favorite sweater by using it to wrap a dog’s leg after it is caught in a bear trap.
5. A supermarket checkout employee (Y) makes X wait for 2 min, while Y takes a phone call to discover how his parent fared in open-heart surgery (benefit to Y much higher than cost to X).

In each case, Y must decide whether to impose that cost on X or not.

What kinds of factors should determine Y’s decision? In theory, these decisions will be informed by variables that relate to the ancestral costs and benefits of making these decisions. From the review of the animal literature above, one would predict that individuals become less likely to impose a cost on an individual as the size of the cost increases and as the size of the benefit one receives decreases, e.g., you become more likely to take a contested food item when you are hungry and when they are satiated. In addition to these transient variables, there are stable variables that are operative across many conflicts of interest,

e.g., kinship, bargaining power, and cooperative history (Nowak 2006). These variables would need to be integrated by the individual in order to make an actual decision, i.e., a man could not refrain from imposing the cost on his brother because of kinship, while simultaneously imposing that same cost because his brother is less formidable. Evolutionary psychologists have argued that humans evolved to compute and store a summary variable or function that integrates these factors for each individual that the person interacts with (Sell 2011; Tooby et al. 2008). In other words, this stored variable indicates the weight one person puts on the well-being of another; it answers the question, “Compared to myself, how much do I care about him?” This variable has been termed the *welfare trade-off ratio*.

The Welfare Trade-Off Ratio

The value one individual places on the welfare of another is indexed by their welfare trade-off ratio (WTR; see Sell et al. 2009b; Tooby et al. 2008). The WTR that Y has toward X (WTR_{yx}) indicates the extent to which Y will allow costs on themselves in order to benefit X and the extent to which Y will impose costs on X for Y’s own benefit, i.e., $WTR_{xy} = \text{benefit}(X)/\text{cost}(Y)$. The mathematics of the welfare trade-off ratio is identical to Hamilton’s rule, the asymmetric war of attrition, and other models of selection (Nowak 2006) that use ratio variables to delineate a limit on cost-benefit transactions. But there are key differences between these models and the welfare trade-off ratio. Hamilton’s rule, for example, is a model of how natural selection will act on genes, but the welfare trade-off ratio is a model of human cognition. Hamilton’s rule is not instantiated in the world but rather summarizes what happens to genes based on their effect on organism’s reproduction. Hamilton’s rule does not need to exist in the brain of any animal (Dawkins 1979). The WTR model, on the other hand, is theorized to exist in neural form in the brains of humans, and it regulates behavior in that individual.

An individual will have different welfare trade-off ratios for different individuals. For example, a person might be willing to ruin a stranger’s favorite sweater to dress their pet’s wound but

unwilling to ruin the dean’s sweater for a similar reason. An individual may be unwilling to give several thousand dollars to pay for a stranger’s education but willing to spend that amount on their own child’s education. This ratio can be seen as a threshold (the dotted line in Fig. 1), above which agent Y would relinquish the benefit rather than impose the cost on X and below which Y would impose the cost on X to receive the benefit. This ratio is Y’s welfare trade-off ratio with respect to X – as it indicates the extent to which Y is willing to trade off his own welfare in order to raise X’s and vice versa. In this case, he would not be willing to ruin X’s car to avoid paying a speeding ticket (1 is above the line), but he would be willing to make X wait in line while he called the hospital to check on a loved one (5 is below the line).

From a selective point of view, and ignoring cases of kin and the complicated nature of human cooperation, natural selection can be expected to have designed humans to adopt the lowest possible welfare trade-off ratio toward others (i.e., impose any cost in order to get even a meager benefit). But given the costs of contests and the nature of kin and competition, natural selection is predicted to have designed humans such that welfare trade-off ratios will be set higher based on numerous factors related to another’s ability to enforce their own welfare, just as with other animals. One set of factors is related to the ability to enforce WTRs by threatening to inflict harm: these include, e.g., greater physical strength and more coalitional support. Another set of factors is related to the ability to enforce WTRs by threatening to withdraw the benefits of cooperation: these include, e.g., the person’s status as a frequent and dependable reciprocation partner, their status as a friend who has a stake in your welfare, or their possession of special abilities that can be deployed to benefit others (Tooby and Cosmides 1996).

It is likely that there are at least two types of welfare trade-off ratios that govern cost-benefit transactions in different contexts: (1) extrinsic welfare trade-off ratios, which define the threshold of cost-benefit transactions when both parties are present or otherwise capable of defending their interests, and (2) intrinsic welfare trade-off ratios,

which define the threshold of cost-benefit transactions when the other individual is not present or unable to defend their interests. Intrinsic WTRs allowed individuals to adaptively partition cost-benefit transactions in a world where the welfare of other individuals was of adaptive significance for oneself. Although the full selection pressure analysis of intrinsic WTRs is beyond the scope of this entry, a quick starting point would be as follows: a subset of individuals in one's social world can improve one's welfare as a result of their existence, social power, and well-being (e.g., a devoted friend, a caretaker of one's children, a generous acquaintance, etc.). Benefits given to them, even without their knowledge, will correspond to benefits to oneself (see Tooby et al. 2008).

Those cases notwithstanding, an individual human is born into a world populated by others who, under most circumstances, are designed to give as little as necessary to the individual (i.e., to have low welfare trade-off ratios toward others, such that they would be willing to impose large costs on that individual for even small benefits). There would have been constant and powerful selection for an individual (X) to raise the WTRs that others used in their interactions so that the other would forgo some cost-benefit interactions that imposed costs on X and proceed with cost-benefit transactions that granted benefits to X. The higher the other's WTR can be pushed up, the more costs X can avoid. Thus, one could predict that natural selection would have designed a mechanism with the following design features:

- The mechanism should come online when there are indications that another individual does not value X's interests highly.
- That mechanism should gather the attention of the target and open a channel to the cognitive structures that calibrate WTRs.
- This mechanism should then feed information to these cognitive structures, information specifically designed to upregulate the target's WTR toward X.
- Such information could include threats or demonstrations of fighting ability, threats to withdrawal benefits or demonstrations of cooperative

value, indicators of kinship, and appeals to third-party judgment and coalitional support.

- The mechanism should turn off when there are indicators either that the target does indeed hold an appropriate WTR or that the target has recalibrated their WTR upward.

The recalibrational theory holds that this evolved mechanism is anger.

Computational Design of Anger

First, a quick sketch of the recalibrational theory will establish its primary components. This entry will then review how the recalibrational theory can explain the major features of human anger and then a more thorough description of how the model of anger can be used to explain the major features of the emotion.

Sketch of the Computational Structure of Anger

According to the recalibrational theory, anger is triggered when an individual perceives that another does not value their interests highly enough. The angered person feels entitled to a certain welfare trade-off ratio from the target ("expected WTR" or "eWTR") but observes evidence that the target holds a lower WTR ("observed WTR" or "oWTR"). When $eWTR > oWTR$, anger is triggered. See Fig. 2.

Expected WTRs correspond to intuitive notions such as entitlement and are believed to be calibrated to a large extent by the individual's bargaining power. Individuals with more bargaining power can demand better treatment from others and will thus become angry over a greater range of offenses (i.e., eWTR is more likely to exceed oWTR because eWTR is quite high). For example, because bargaining power in men was highly related to their personal fighting ability during our evolutionary history, physical strength and other indicators of fighting ability calibrate men's sense of entitlement and correspond to lower thresholds for anger (Lukaszewski 2013; Sell et al. 2016; Sell et al. 2009b; Salas-Wright and Vaughn 2016). Indeed, entitlement

Recalibration Theory of Anger, Fig. 2 The recalibrational theory of anger

generally is related to lower thresholds of anger (Bushman et al. 2009).

Observed WTRs are computed by the angry person from indicators that another individual does not value the angry person's welfare highly. The clearest case of this is when an individual imposes a large cost on another in order to receive a small benefit. Recall that WTRs relate to the maximum cost-benefit ratio an individual will impose on another (i.e., $WTR_{xy} = \text{benefit}(X)/\text{cost}(Y)$). So a low WTR_{xy} is indicated when $B(X)$ is small, e.g., your friend wastes your time to finish playing a video game, and when $C(Y)$ is large, e.g., you are waiting on him to take you to the hospital.

Once the anger system detects that the observed WTR is lower than the expected WTR, attention focuses on the incident, and a stream of mental computations is run that reevaluates the variables related to the observed WTR in order to determine if the observed WTR accurately represents the target's actual or real WTR toward the angry person. This is called *stage 1* anger (Sell 2011), which functions to bargain over a given conflict and determine if the target of anger actually holds a low WTR toward the angry person or if their actions reflect a misunderstanding and a temporary condition or are in fact consistent with

a higher acceptable WTR (i.e., does the observed WTR inherent in the target's actions accurately reflect their real WTR). Stage 1 anger is frequently characterized by an interrogation of the target of anger. For example, when the observed WTR is indicated by the prototypical imposition of a large cost for a small benefit (e.g., the angry woman's husband left her stranded at the airport while he was talking on the phone), the angry person will inquire about the magnitude of the cost imposed and the target's knowledge of that magnitude, e.g., "Did you know you were supposed to pick me up at the airport?", and the magnitude of the benefit, "You better have been talking to President Obama or the Pope!" The angry person will attempt to correct misperceptions of these variables to win the conflict (or similar conflicts in the future), e.g., "For the future. . . don't ever leave me stranded at the airport again! It's really disrespectful."

If the anger system determines that the observed WTR was not an accurate indicator of the target's actual WTR toward the angry individual, then anger will stay in stage 1 and may bargain over the conflict in particular, e.g., "Well next time let me know you'll be late at least." If, on the other hand, the target reveals that the observed WTR accurately indicates their true WTR toward the

angry person, then anger can escalate into stage 2, e.g., “I knew I was supposed to pick you up, but I felt like talking to Sue. And no, I won’t apologize for it.”

Stage 2 anger functions to recalibrate the target’s welfare trade-off ratio and is experienced as a more extreme form of anger. This recalibration is accomplished by feeding information to the WTR-setting machinery in the target. Specifically, anger recalibrates the target’s WTR by demonstrating the ability of the angry person to inflict costs (i.e., aggression) or the ability to withhold or curtail benefits (Sell 2011; Williams et al. 1998), because WTRs are calibrated by estimates of bargaining power such as physical formidability, cooperative value, coalitional support, and so on (Lukaszewski 2013; Sell et al. 2009b; Sell et al. 2016; Tooby et al. 2008). The strategies can “work” because the WTR-setting machinery in the mind of the target is designed to calibrate WTRs in response to the bargaining power of the other individuals. As with nonhuman animals demonstrating their fighting ability, these displays start with low-cost, presumably less accurate, demonstrations and escalate as needed to more accurate and dangerous behaviors.

The Recalibrational Theory and Features of Anger

This simple sketch of human anger serves as a framework for more specific subtheories about the features of anger, e.g., the triggering conditions of anger, the function of the universal anger face, and the calibration of thresholds for anger.

The Triggering Conditions of Anger

According to the theory, the primary activating conditions for anger will be cues that indicate another individual maintains a lower welfare trade-off ratio than is acceptable given their negotiated relationship. These cues exist in many formats because the WTR is likely to be used by many different cognitive mechanisms. That is, how much weight a person puts on another’s welfare may “leak” through many channels. This explains why anger can be triggered by so many computationally distinct indicators. For example, the degree to which one values the welfare of another

presumably regulates the fidelity of memory encoding such that information about an individual who is highly valued is more likely to be remembered. Thus, ignorance about a person can indicate a low WTR toward that person and activate anger in them. Ignorance is a less common trigger of anger though. The work by Averill (1982) identified the most common trigger of anger as that of a cost imposition.

By definition, cost-benefit transactions contain within them the implicit maximum WTR the cost imposer holds. Specifically, when actor X imposes a cost on Y in order to receive a benefit, the maximum WTR X has toward Y (i.e., WTR_{xy}) is (benefit to X)/(cost to Y). Thus, the maximum WTR that X has toward Y becomes lower as the cost imposed on Y increases and the benefit X receives as a result of that cost decreases. See Fig. 3.

Consistent with these basic predictions, cross-cultural studies demonstrate that subjects become more angry as the cost imposed on them increases but less angry as the benefit to the other individual increases (Sell et al. *in press*). In other words, as the observed WTR lowers, anger becomes more active.

Welfare trade-off ratios can also be revealed when individuals refuse to grant benefits at a cost for themselves or impose costs on others to benefit third parties and so on. Furthermore, because humans have metacognitive abilities, a cost-benefit transaction does not need to actually be enacted in order to indicate a low WTR. If an individual attempts, plans, or in some cases even considers at some length, imposing a large cost on an individual for a low benefit, this can reveal one’s WTR. For example, imagine a medical swindler who approached a man and offered to buy his wife’s lungs. The swindler promised that she would be put down humanely. If the husband considered this proposal for more than a fraction of a second, one would assume that his valuation of his wife’s welfare was far too low, even if he did not ultimately decide to sacrifice her life.

Sell (2014) analyzed a large set of anger-based arguments and categorized them into 12 computationally distinct triggers of anger, each of which is a plausible (albeit currently unproven) predictor of holding a low WTR toward the angry person:

Recalibration Theory of

Anger, Fig. 3 A lower
WTR_{xy} is indicated as C
(y) increases and B
(x) decreases

1. Cost-benefit transactions (see above).
2. Insulting beliefs. The target of anger indicates that they evaluate the angry person low on a trait relevant to the setting of WTRs (e.g., “Do you think I’m stupid?!”). A prediction of this model is that anger-provoking insults will cluster largely around the two primary negotiative tools that are used to set WTRs: the ability to impose costs (e.g., being weak, cowardly, socially impotent) and the ability to confer benefits (e.g., unreliable, a cheat, unable to gather resources, low mate value, incompetent, sickly, a burden on others).
3. Co-opting decisions. The target of anger makes decisions for the angry person.
4. Social rejection and jealousy. The target of anger indicates a willingness to disengage from the angry person or indicates that such a disengagement would be low cost for the target, e.g., “I don’t really need you. . .”
5. Maintaining divergent goals. The target of anger indicates that they are seeking or will seek goals incompatible with the angry person, e.g., the target of anger could support the “wrong” political position or candidate.
6. Lack of inherent value in being together. The target of anger indicates that they do not sufficiently enjoy the angry person’s company.
7. Respecting rivals or disrespecting allies. The target of anger treats the angry person’s enemies too well or fails to value friends of the angry person.
8. Lack of empathy. The target of anger fails to exhibit concern over the suffering of the angry person. The target need not have caused the suffering, e.g., “Do you want to see the new Bond movie?” “I can’t; I just found out my mother has cancer!” “Oh. Maybe a comedy then?”
9. Lack of self-disclosure. The target of anger fails to “trust” the angry person with information about themselves.
10. Lack of memory. The target of anger fails to remember information about the angry person.
11. Deception used to win a conflict of interest. The target of anger lies to the angry person in ways that indicate that they do not “trust” the angry person, e.g., “I would have loaned him my car anyway. . .he didn’t have to lie!”
12. Arrogance. The target exaggerates (intentionally or unintentionally) their bargaining power or other trait that calibrates welfare trade-off ratios, e.g., “Sometimes I feel like the only intelligent person in the room.”

These triggers – in theory – all respond to different uses of the WTR, e.g., WTRs are used to make cost-benefit decisions (#1) but also regulate memory for important people (#10). Therefore, different variables will predict how high or

low the WTR is for different triggers of anger. For example, if you were to spill your colleagues' coffee on their pants, their anger system would respond much less aggressively if your actions were unintentional. But if your colleague was angry because you thought their latest paper was inept and stupid, their anger would not be assuaged if you indicate that you did not "intend" to think their paper was stupid. This is because anger triggered by cost-benefit interactions (e.g., spilling coffee on them for no real benefit) only indicates WTRs precisely if the target considered the cost and benefit and then decided to implement the cost. Their WTR toward the angry person is "leaked" accurately only when they knew these variables, weighted them, and then decided. But if you believe your colleague is unprofessional or incompetent, then saying that you did not "intend" to know they were terrible does not remove the accurate indicator of your WTR toward your colleague because believing that your colleague is deficient on a WTR-relevant factor (#2) would lower your WTR toward them whether it was intended or not.

Because there are multiple channels that leak information about WTRs, actions can sometimes indicate a high WTR through one channel but low WTR through another. For example, anger can be triggered by a cooperative partner's willingness to replace you (#4 above) because WTRs toward friends and romantic partners are indicated – in part – by one's estimated longevity of the relationship (Tooby and Cosmides 1996). Therefore, if a man were caught cheating on his wife, and she confronted him, her anger can be triggered by two simultaneous channels: one, she is angry because he indicated a willingness to replace her with another woman (#4), and two, she is angry because he engaged in an act that imposed a large cost on her for a relatively small benefit (#1). The other woman's attractiveness then modulates anger via both channels but in opposite directions. If the other woman was extremely attractive, this intensifies the signal through the jealousy channel, i.e., it indicates that he is more likely to replace his wife with the other woman. On the other hand, if the other woman was unattractive, it would intensify the cost-infliction channel by

indicating that her husband decided to impose this painful cost on his wife for a trivial and untempting benefit. This leaves the husband with two opposite arguments, both of which backfire by exacerbating anger via a second channel: "You don't understand; she was just so amazingly attractive!" or "She was ugly and smelled of garbage and bad judgment, but I threw our marriage away anyway..."

Factors that Trigger Escalation of Anger

Anger is expensive in both metabolic terms and social costs (e.g., retaliation, counter-bargaining by the target of anger). Furthermore, estimating another's WTR is fraught with error. Therefore, the first response of the anger system is usually to seek information from the target to refine the observed WTR estimate and give the target of anger a chance to explain why their actions do not indicate a low WTR. This is part of stage 1 anger in the recalibrational theory (Sell 2011). In addition to seeking confirmatory evidence of a low WTR, stage 1 anger can negotiate conflicts of interest in the short term without renegotiating the welfare trade-off ratio itself.

For example, in cost-benefit transactions, an individual in stage 1 anger can argue that the cost to them of the transaction is very high, and the benefit to be received by the target of anger is too low. Imagine two fraternity members arguing about which movie to watch in their dorm room. Arguments would include statements about the relative value of both movies (e.g., I've seen that already and my movie is rated 4 out of 5 on Rotten Tomatoes), turn-taking (e.g., we watched that train wreck of a movie you recommended last week), and other aspects of conflict negotiation. However, what will be absent in stage 1 anger are the kinds of negotiations used to recalibrate welfare trade-off ratios themselves. If during the fight one of them said, "You know I can kick your ass!" or "Nobody here even likes you" or "Fine, good luck driving yourself to the airport next week," both interlocutors would realize that the speaker's anger had escalated because those arguments are designed to illustrate bargaining power and are used to recalibrate welfare trade-off ratios (i.e., they are part of stage 2 anger).

During stage 2 anger, the angry individual will deploy strategies to recalibrate the target's WTR. To do this, the anger system must deliver information to the WTR-setting mental machinery of the target. This information must be in a format that is computationally intelligible to that system; in other words, the tools that anger can use to recalibrate WTRs are limited to the variables that set WTRs to begin with. WTRs are calibrated largely by bargaining power: the ability to impose costs and the ability to deny benefits. This means that anger could evolve at least two strategies to recalibrate the target's WTR, bargaining aggression, and cooperative withdrawal.

Bargaining Aggression

Anger-based aggression is distinct in form and function from other kinds of human aggression (e.g., warfare, hatred-based aggression, defensive aggression). According to the recalibrational theory, anger-based aggression is primarily designed to recalibrate the target's estimate of the angry individual's formidability (i.e., ability to impose costs). Such aggression is characterized by many features consistent with that function:

- (i) Anger-based aggression is frequently announced to the target with verbal threats, voice modifications, and a universal anger face (see below). Such announcements enable the target to direct attention to the angry individual and assess the demonstration of formidability, and they enable a low-cost means of success if the target immediately recalibrates under the threat.
- (ii) Anger motivates approach toward the target in an attempt to gather the target's attention for the same reason.
- (iii) An individual aggressing from anger will typically abstain from more lethal or damaging attacks, but instead focus on demonstrative actions, e.g., pushing, shoving, hitting, or throwing inanimate objects, slaps, strikes to less vulnerable parts of the body, and non-weaponized aggression. Retaliation may lead to escalation in the lethality of the fight (Luckenbill 1977), but the initial aggression is almost always

sublethal and only escalates if the target fails to capitulate (Luckenbill 1977).

- (iv) Anger-based aggression often allows for explicit turn-taking or "rules" (Romero et al. 2014) so as to allow for mutual assessment of formidability.
- (v) Aggression subsides (indeed anger subsides) when the target of anger recalibrates and apologizes, illustrating that the function of this aggression is to provoke recalibration not inflict harm itself.

These features are consistent with ritualized aggression (or "escalating conflicts of assessment" or the "sequential assessment game") in nonhuman animals (Enquist et al. 1990; Huntingford and Turner 1987). Evolutionary biologists understand them as attempts to modify status calculators in the brains of their opponents. Both animals fight in a way that enables them to estimate the fighting ability of their opponents while minimizing the severity of injury. As with other nonhuman animals, these fights are frequently preceded by poses and body configurations that enhance cues of fighting ability in order to win conflicts of assessment early (e.g., dewlap inflation, bared fangs, piloerections). According to the recalibrational theory, the universal human anger facial expression evolved to perform this same function (see below).

The Function of the Anger Face

The universal human anger expression (Ekman 1973) is composed of distinct muscle movements that can be coded into facial action units (e.g., the brow lowers, the lips thin). The expression is cross-cultural, present in congenitally blind children, and distinct from chimpanzee expressions and shows other hallmarks of being an adaptation designed by natural selection (Sell et al. 2014).

The function of this adaptation, according to the recalibrational theory, is to enhance cues of physical strength that exist in the face. Previous research shows that such cues are readily apparent, e.g., humans can accurately estimate a man's upper body strength from photographs of his face (Sell et al. 2009a). The anger face modifies some of these cues of strength by a targeted flexing of

Recalibration Theory of Anger, Fig. 4 The anger face enhances cues of physical strength

the facial musculature. The result is a face that appears more physically strong. Sell et al. (2014) demonstrated this by showing that each component of the anger face – independently – increased the perceived strength of the face. In other words, the anger face itself is an evolved constellation of muscle movements that, like ritualized enhancement displays in other animals, enhances cues of physical strength during conflict (see Fig. 4.).

Cooperative Withdrawal

Although theories of anger have focused on aggressive behaviors as the primary action motivated

by anger (see Potegal and Spielberger 2010), the data suggest that aggression is rarely deployed during a bout of anger. Averil's survey, for example, showed that less than 10% of incidents of anger recalled by his subjects reported even the explicit threat of aggression (Averill 1982).

Why is anger so rarely aggressive? According to the recalibrational theory, anger-based aggression is designed to recalibrate the target's welfare trade-off ratio, and this can work because welfare trade-off ratios are responsive to estimates of another's fighting ability, i.e., one way to make an individual value your interests is to demonstrate

that you can hurt them if they do not. However, given the cooperative nature of human interactions, there will be many individuals who value your welfare for reasons that are unrelated to fighting ability, e.g., a couple with a child may value one another based on their commitment to the child's welfare, friends may value each other based on a history of reciprocity, and so on. If the nature of the relationship between the angry individual and the target of her anger is such that the target's welfare trade-off ratio is primarily calibrated by variables other than fighting ability, then aggression will be an inefficient means of recalibrating the target.

In such relationships, anger uses other behaviors to recalibrate the target. Most commonly, if the relationship is based on cooperative value, the angry individual can threaten or actually withdraw cooperation (Williams et al. 1998). Such a demonstration would work for the same reasons that demonstrations of formidability will work: by withdrawing cooperation, the angry individual demonstrates to the target that they will be worse off by continuing to treat the angry individual with such little regard.

As with conflicts of assessment and ritualized aggression, these bouts of cooperative withdraw are predicted to follow a pattern that enables individuals to demonstrate cooperative value in ways that minimize the damage done by the demonstration. In other words, just as two cichlid fish avoid biting but engage in tail-beating during a fight (Enquist et al. 1990), and two men punch and kick in a bar brawl but avoid eye-gouging (Romero et al. 2014), two feuding spouses may withhold chores and affection but would still rush to one another's aid if they were in a serious accident. These bouts of cooperative withdraw are predicted to be coupled with monitoring and other evaluations to determine changes in the mental state of the target of anger. This often leads to odd situations where an angry individual is abstaining from cooperative behavior and withholding attention, i.e., simulating to the target what it would be like if the cooperative pattern was ended, while actually focusing a great deal of attention on the target.

One prediction from this model is that individuals with greater cooperative value – those whose cooperation is of greater benefit to others – should

calibrate their expected welfare trade-off ratios higher. In other words, they should expect and demand better treatment from others, just as those with greater formidability are known to do. This has been confirmed empirically for several traits related to cooperative value, specifically physical attractiveness, wealth, and mate value (Lukaszewski 2013; Sell et al. 2016; Sell et al. 2009b).

The Content of Anger-Based Arguments

Though rarely empirically studied, arguments are, by far, the most common behavioral response to anger (Averill 1982), and any comprehensive theory of anger must ultimately explain the structure of such arguments. The recalibrational theory explains arguments as the mutual recalibration of variables that are relevant to the resolution of the conflict (e.g., relative value placed on the contested resource) and to the calibration of the individuals' welfare trade-off ratios. This information exchange has many evolutionary precedents, e.g., some species are known to send signals of their valuation of a contested resource. Bald eagles raise their crop to show the distention of their gullet to opponents when fighting over food (Hansen 1986). While eagles signal their hunger via a different channel than a human bargaining over whether he is allowed to take the day off of work, the cognitive grammar of the message is identical: "I value this highly, and therefore you should cede the conflict to me." Such an argument will sometimes recalibrate the opponent and lead to the resolution of the conflict in favor of the arguer, e.g., bald eagles that see the empty stomach of their opponent are more likely to relinquish the food (Hansen 1986).

Conclusion

According to mainstream evolutionary psychologists (Tooby and Cosmides 1990), emotions are evolved modes of operation that function to coordinate multiple systems of the body and orient them toward a temporary adaptive problem, e.g., fear coordinates attention, sensory input, and bodily responses and calibrates them toward the adaptive problem of imminent bodily

harm. The recalibrational theory of anger (Sell 2011; Sell et al. 2009b) is an evolutionary psychological theory that claims that anger evolved by natural selection to bargain for better treatment. This selection pressure has designed many bargaining systems in nonhuman animals, and these systems serve as phylogenetic precedents for anger.

The structure of anger itself appears well designed to bargain. Anger is triggered by indications that a target does not value the angry individual's welfare highly (i.e., the target has a low welfare trade-off ratio (WTR) toward the angry individual). These indications usually start in stage 1 anger where the angry person interrogates the target and bargains over the conflict itself. Anger can escalate into stage 2 anger when it is revealed that the target of anger does indeed hold a low WTR toward the angry individual. In stage 2 anger, the angry individual attempts to recalibrate the target's WTR by demonstrating an ability to harm the target by cost infliction (i.e., aggressive bargaining) or benefit withdraw (i.e., cooperative withdraw).

The recalibrational theory has many strengths. Specifically, it offers a specific computational analysis of human concepts like "status" and "disrespect." The theory is derived from well-understood and validated models of animal bargaining that have helped understand aggression in many other species. Furthermore, because it is a functional theory (rather than descriptive), it can be used to derive multiple subtheories about aspects of anger, such as the theory that the anger face is composed of muscle movements that enhance cues of strength. Finally, it has the potential to explain the largest unresolved issue in anger research: the computational design of anger-based arguments.

There are also limitations and weaknesses of the recalibrational theory. It cannot easily account for anger deployed at inanimate objects (e.g., a boy repeatedly fails to climb a tree and seemingly becomes angry at it) or anger at the self. Furthermore, the theory of anger depends on the computational structure of status-setting machinery (e.g., the welfare trade-off ratio and how it is calibrated) for many of its predictions. Until this status-setting machinery is well understood, the predictions about anger will be tentative.

Definition

Memory for others is enhanced by details violating one's social expectations.

Introduction

All too often we encounter individuals engaging in behaviors that go against societal expectations. In a recent survey report, over one-third of graduate students, over two-thirds of college undergraduates, and over 90% of high school students admitted to knowingly cheating or plagiarizing academic work (McCabe 2017). As another example, we know that rates of cheating among married couples range between 2% and 4%, with infidelity being cited as the most common cause for divorce (Fincham and May 2017). Certainly, academia and romance are not the only examples in which deception can be encountered. Although engaging with individuals who have behaved in a socially deviant fashion may not always be avoidable, through evolution we have evolved mechanisms that assist in minimizing the potential negative impacts from these associations. Are such mechanisms specific to remembering socially deviant individuals, or are they more broadly employed?

Memory allows individuals to reflect upon and learn from information previously encountered. According to an evolutionary perspective, the skill of recollection has evolved as an adaptation that aids an individual in navigating his or her environment with the aim of genetic proliferation (see Confer et al. 2010; Cosmides and Tooby 1997, for primers). This idea of adaptive memory has gained momentum over the past decade with the underlying notion that information most relevant to survival (e.g., locating food and shelter, protection from predators, and identifying personal safety) demonstrates a prioritized place within memory (Nairne et al. 2007; Scofield et al. 2018). In this framework, the details of individuals who pose a threat have also been shown to induce efficient processing in observers. This efficiency encourages constructive social interactions to occur in the future, whether that means to engage with or retreat from such individuals.

As social beings, it is imperative for humans to have the ability to successfully recollect the faces of others. The results from early research (e.g., Mealey et al. 1996) on memory for others' reputations have focused on the presence of a processing system specifically adapted to detecting noncooperative individuals (e.g., cheaters). However, the extant literature instead suggests that superior memory recall for cheaters can be explained by a host of alternate variables.

A Memory Focused on Cheaters?

Socializing holds a possibility for immense rewards and severe costs. When interacting with others, we may mentally calculate the potential costs (e.g., losing resources, being harmed) and benefits (e.g., gaining resources, protection) to arrive at a decision as to whether or not we should engage and the degree of caution to take (Balliet et al. 2011). The act of cooperating with others can mean that an individual must accept a certain number of costs in order to help others and obtain a desired set of benefits.

While there may be a mental trade-off of potential outcomes, some have suggested that people

often behave in a way that is honest, fair, and beneficial to both parties (Axelrod and Hamilton 1981; Trivers 1971). One such highly-cited example comes from social contract theory (Cosmides 1989; Cosmides and Tooby 1992, 2005). This theory holds that unrelated persons engaging with each other hold an agreement to act in a moral and socially acceptable fashion. That is, we assume others will behave in a way that is honest, fair, and beneficial to both parties.

However, not all individuals encountered will act in such a cooperative fashion. When a person breaks a perceived contract, they may be acting with self-serving motives that disadvantages at least one party. Social cooperation is key when it comes to positive interactions with others (c.f., Gómez-Gardenes et al. 2012). Just as it can be advantageous to identify individuals with a history of cooperation, those with a history of non-cooperation should be detected and remembered with importance so as to minimize the chance of deception during future encounters. As such, one could identify individuals with a history of cheating or cooperative behaviors to appropriately avoid or seek out these individuals during social situations, respectively.

Aligning with the conceptual ideas of social contract theory, Cosmides and Tooby (1992, 2005) have posited a cheater detection module. This highly popularized account predicts that humans have adapted a particular attunement of attention and memory toward the cheaters within one's environment. This attunement is thought to occur whenever a situation involves social contracts, regardless of context. During a social exchange, it is predicted that other's reputations will be keenly remembered when a history of deception is perceived. When a person behaves in a way that goes against societal norms, such as cheating or acting noncooperatively, they may be particularly memorable due to the expectation violation (Kroneisen and Bell 2013).

It can be argued that unexpected events require one to utilize additional cognitive resources and effort in order to understand a situation that would otherwise be automated and simple. For example, stereotypes (a commonly held belief about a group of individuals) allow for information

about others to be processed quickly based on assumptions. However, instances that violate these biases can induce atypical and critical thinking (Rudman and Fairchild 2004; Sekaquaptewa and Espinoza 2004). In short, the prospect of being unfairly deprived of personal resources poses a specific threat that evolutionary pressures have selected for in shaping our modern cognitive abilities. The pillars of a cheater-detection module, generated from social contract theory, assume that human cognition developed to solve the specific adaptive problem of exploitation by cheaters.

Indeed, it is not difficult to imagine how recollection for those with a history of cheating could be advantageous from an evolutionary standpoint (Bell and Buchner 2009; Drigotas and Barta 2001; Mealey et al. 1996). Yet, if true, a question emerges as to why might memory for cheaters be enhanced, as compared to memory for cooperators?

A person who displays cooperative behaviors, such as fairly sharing resources or helping an ill family member, becomes associated with the notion that continued engagement with such an individual would be beneficial (Orbell and Dawes 1991). An individual who acts in a self-serving and noncooperative fashion, such as one who steals resources or does not follow through on an agreement, can be labeled as non-desirable or a “cheater.” The label of “cheater” can potentially frame future interactions with distrust. Such framing may even result in a decreased propensity to engage in future interactions.

While the label of “cheater” can dissuade people from future interactions, the label of “cooperator” may not be as diagnostic in indicating how to proceed. An individual who cheats in a given circumstance may have motivation to behave in a more socially desirable fashion in an alternative context (Axelrod and Hamilton 1981; Trivers 1971). For example, a person who unfairly trades resources with a stranger may choose to trade fairly with a friend who supplies a highly desirable item. A known cheater may act in an unpredictable fashion depending on situational context, but a known

cooperator is presumed to behave fairly regardless of circumstance.

Without an expectation of negative behavior, it seems we may assume others should behave cordially. Thus, cognitive resources may not be taxed by remembering cooperators: it is not harmful to interact with such individuals. However, additional effort could be required to remember unexpected deceptive behaviors, such as cheating. Moreover, the potential harm associated with forgetting a cheater (i.e., potential threat) is greater than is associated with forgetting a cooperator (i.e., potential help). In short, a reputation of cheating (displayed only by cheaters) is more diagnostic of future behavior than is a history of cooperation (can be displayed by both cheaters and cooperators). A memory tuned toward remembering cheaters and their reputations, as opposed to cooperators, is beneficial to avoid exploitation. Therefore, recognition (i.e., sense of familiarity) alone is not useful when engaging in social exchanges. Rather, the ability to recollect specific details of an encounter is essential for creating an association between a face and its behavioral history. Being aware of such an association can then be one component used to frame future interactions.

In summary, it has been argued that cheaters hold special value in evolving human cognition. Both the social contract theory and the cheater detection module predict that a superior memory for such noncooperative persons is the result of an evolutionary adaptation that allows for the detection of societal norm violations. If memory is indeed *not* specific for cheating behaviors, what more general mechanisms does it most readily process? The following sections will discuss how reputational memory is studied, followed by discussions of two main points of consideration: expectation violations and context relevancy.

Empirical Testing of Reputational Recall

Memory retrieval is typically studied in one of two methods: recognition (familiarity based) and

recall (recollection of details). The first instance of empirical examinations of memory for cheaters was provided by Mealey et al. (1996) using tests of recognition. Specifically, participants were asked to rate a series of photos of Caucasian males on their level of physical attractiveness. Importantly, descriptive information presented with each face indicated varied information about their social status (high or low) and general character (potential for cheating behaviors). A week later, the participants again viewed the images and were asked to indicate which faces they recognized from the previous session. Mealey and colleagues reported that participants were most accurate at identifying photos of individuals previously associated with cheating behaviors (e.g., caught embezzling money) than with trustworthy behaviors (e.g., returned a lost wallet). However, this pattern of results was mitigated for faces also associated with a high social status, who were viewed as more attractive overall: high-status individuals are well-recognized regardless of their behavioral history. The researchers concluded that faces associated with potential threat, particularly those of low-status individuals, produce a *recognition memory* attunement. This landmark research provided interest and evidence for understanding the influence of reputational status and character variables on memory prioritization.

However, such a memory advantage for cheaters has largely gone unreplicated (e.g., Barclay and Lalumière 2006; Bell and Buchner 2009; Bell et al. 2012; Mehl and Buchner 2008; Schaper et al. 2019). Recent experiments designed to assess reputational memory (i.e., remembering patterns of past behaviors) have employed variations of a face and description encoding task followed by a recognition and source memory test. One example of the common paradigm (Bell and Buchner 2009) tasked participants with rating the likability of faces presented together with behavioral descriptions that implied either positive (e.g., trustworthiness: a cheese monger who allows his customers to sample his products), negative (e.g., cheating: a used-car

dealer who conceals serious defects from his customers), or neutral (e.g., reputational irrelevant: a scaffolder who works where buildings are to be constructed) actions. Later, a standard recognition task was administered in which participants indicated if a given face had been previously presented or not, depicting a sense of familiarity with the individual. When a face was identified as previously rated, the participant also recalled the source memory by indicating the details of the associated behavior (i.e., cheating, trustworthy, or irrelevant).

The results of the *recognition* task indicated no difference for facial memory between those previously rated. Evidence supporting a lack of advantage in recognition memory based on cheater status has since been routinely found and is in contradiction to the conclusions reported by Mealey et al. (1996). However, patterns of differentiation emerge when asked to *recall* the nature of the specific behavioral description (source memory) associated with a previously rated face: faces associated with cheating behaviors were better remembered than those associated with trustworthy behaviors, which surpassed those associated with irrelevant behaviors.

The expansive literature regarding reputational memory challenges the merit of a true cheater detection module. Two main arguments have emerged against the presence of a cheater-specific cognitive adaptation. First, the mere identification of a cheater as having been previously encountered is not enough to avoid the possible repercussions of an interaction. Research has indicated that merely re-meeting an individual, regardless of their behavioral history, can increase trust and perceived importance due to a sense of familiarity with that person (Jacoby et al. 1989; Zajonc 1968). Therefore, it seems imperative that one cannot only detect a devious individual, but can also accurately associate that person with the correct behavioral history.

Second, it has been argued that a sole focus on the actions of cheating individuals does not produce a complete picture for successful interactions with others. That is, it is personally advantageous

to remember those who have demonstrated untrustworthy actions so as to avoid future deception. Similarly, there is a personal advantage to remembering people who demonstrate trustworthiness to continue engaging in reciprocal benefits (Bell et al. 2017). Indeed, after learning the likelihood that a given partner will cooperate with or act unfairly in a given task, individuals display a preference of willingness to engage with those who act in a mutually beneficial fashion (Schaper et al. 2019; Winke and Stevens 2017). Choosing to focus on cheaters or cooperators can be influenced by the contextual circumstances and present goals for the interaction.

While it is important to recognize an individual as having been previously encountered or not, this information alone is not sufficient in determining one's probability of acting in a cooperative or deceptive manner. Accordingly, when asked to indicate if an individual has been introduced before or is a novel stranger, the typical results indicate that there is no benefit to accuracy based on whether the individual was previously a cooperator or not: recognition is equivalent and better for cooperators and deceivers than previously unencountered individuals. However, when asked to identify the context (i.e., source memory) in which an individual was previously encountered (e.g., cooperator or deceiver), differences in *recall* tend to emerge. The variables influencing accurate recall memory for cheaters will be discussed in the next sections.

Violation of Social Expectations

While there is some reason to suspect that a unique base system for cognition has been enhanced to recollect the sources of cheating behavior (Bell and Buchner 2009; Mehl and Buchner 2008; Schaper et al. 2019), others have argued that the enhanced memory is driven by a violation of expectancy – or rather the presence of incongruent information. That is, the seemingly robust human ability to remember cheaters is a result of a more flexible cognitive

system that responds well to surprising information.

On a daily basis, we have expectations for how commonly encountered situations will proceed and for how others will behave in such circumstances. However, when these social norms are violated, the instance goes against our expectation and can produce a memory advantage for the individuals and details involved. For example, it is documented that we tend to quickly evaluate people possessing qualities associated with desirability (e.g., positive affect, physical attractiveness, and high social status) as trustworthy and memorable (Todorov, Pakrashi, and Oosterhof 2009). Such an understanding could, in part, account for the findings in Mealey et al. (1996) for improved *recognition* of high-status individuals, regardless of their cheater reputation: high-status trustworthy individuals were remembered for this desirability, while high-status cheaters behaved unexpectedly.

In the case of reputational memory, knowledge for individuals who violate societal expectations set by social contract rules are markedly perceived as a specific form of expectancy incongruence (Farrelly and Turnbull 2008). For example, Chiappe et al. (Experiment 2; 2004) presented participants with facial photographs accompanied by social contract rules in the form of logic problems that described either cheating (e.g., failed to repay a cost), cooperation (e.g., repaid a cost as agreed upon), or irrelevant (e.g., owes a business) behaviors. Each behavior involved either a relatively large or small sum of money as a means of identifying the influence of resource value. The results of a source memory test indicated that the cheating behaviors were most salient, regardless of the amount of resources involved. The researchers concluded that the threat to the social expectation that an agreement will be fulfilled led to cheaters standing out in memory.

In addition, the literature on memory has established a processing advantage for emotional (valenced) information (Bell et al. 2012; Kensinger and Schacter 2008). That is, events and stimuli that possess a positive or negative

connotation tend to be remembered with greater detail and accuracy than do non-emotional, neutral situations. Moreover, contexts eliciting negative emotions (e.g., sadness, fear) tend to be even more memorable than those eliciting positive emotions (e.g., happiness, trustworthiness; Ochsner 2000).

Encountering individuals with a history of cheating or deceptive behavior can be highly distressing, anger-provoking, and threatening to one's survival (but see Buss et al. 1992 for sex differences). Thus, such persons can constitute a negative context. By having selectively adapted for the ability to remember details of negative memories, humans should show enhanced success in remembering events that resulted in potentially dangerous social interactions. Indeed, faces encountered in a socially threatening context have been shown to be better remembered than faces associated with a cooperative or neutral context (Bell and Buchner 2010; Buchner et al. 2009).

However, not all negative events garner equal memory resources. The context of socially deceptive behavior plays a critical role on its memorability. For instance, consider the relevance that the deceptive action may have on the observer. One study (Bell et al. 2012; Experiment 2) exposed participants to individuals associated with a history of aggressive behavioral tendencies. Crucially, these behaviors were either directed at the observer (e.g., the person gets angry and throws things) or were directed toward the self (e.g., the person gets depressed). During a later memory test, the persons who were associated with behaviors posing a threat to the observer were better remembered as such than were the persons producing aggressive behaviors that only threatened themselves.

Similarly, some researchers have found that memory may be more likely to be enhanced for individuals committing acts of aggression, as compared to victims (Bell and Buchner 2011). In other words, a memory advantage may be most prominent when the act of cheating poses a potential threat to the observer, as opposed to a general bias toward cheating behaviors. The details of

negative events may be associated with threats to the self, enhancing memories for such contexts. As a result, how one recalls noncooperative behaviors could be context specific. The researchers concluded that the lack of equal memorability for threatening behaviors, regardless of the target, indicates a more generalized threat detection system than is posited by the cheater detection module. Rather, the degree to which other people's actions are perceived as threatening must be taken into consideration in creating a functional memory model.

The degree of surprise regarding an expectation violation can also be influenced by the relationship between the cheater and the cheated. That is, people who have a lot of trust in their partner may be most susceptible to the impact of having their expectations violated. For instance, some research has noted asymmetrical reputational memory for uncooperative individuals when they are thought to share group memberships (such as those based on interests and identities with oneself; e.g., common race, social status, teammates) relative to those perceived as outsiders (memberships wherein there is a lack of shared commonalities). Indeed recall memory accuracy was best for *uncooperative in-group members* even though participants assumed that their respective in-group members depicted more cooperative behaviors than did out-group members (Hechler et al. 2016). Thus, the act of deception was thought to be *most* surprising when completed by a trusted in-group member. The results indicated that people tend to trust those associated with having a shared group investment, situating actions that counter this expectation in the forefront of one's memory. The notion of a generalized cheating bias does not accurately encompass such nuanced patterns of results, providing further support for the notion of a more flexible, context-specific memory module.

Some faces inherently display a sense of trustworthiness (e.g., positive valence, attractive), providing that person with a more favorable perception, compared to those with an untrustworthy appearance. For instance, in one study researchers

(Mattarozzi et al. 2015) paired faces that had been rated as trustworthy, untrustworthy, and neutral with newspaper headlines depicting either a pleasant, unpleasant, or neutral action. Importantly, both the photograph and headline appeared simultaneously in an attempt to prevent a bias from the intrinsic appearance of the face. When asked to recall the details of the news article associated with a given face, participants were most accurate when the article elicited emotions (pleasant and unpleasant) than when it was emotionally neutral. In the case of pleasant articles, faces that were rated as either trustworthy or untrustworthy enhanced memory. For the unpleasant news articles, memory accuracy was best when it was associated with an untrustworthy face. This indicates that, without the chance to generate an expectation about others, the emotional context in which a face is encountered largely dictates its memorability. However, the initial interpretations based on facial appearance one has of others can influence memorability for both pro- and antisocial behaviors. Individuals with a threatening appearance are the most memorable, regardless of true behavioral actions. When preconceived expectations about a person are not available, the emotional context of a situation appears to drive memory recall particularly when facial details match the context valence.

When navigating the world and social interactions, it is clear that we are structured toward using mental shortcuts to minimize the amount of cognitive effort exerted. The instances and people that challenge such a shortcut, namely, by violating expectations, seem to cause unique memory processing. However, the degree to which a social violation affects memory is, in part, dependent on the individual observer.

Personal Relevance to Expectation Violations

The ability to recall the reputational history of others has been shown to be influenced in part by relevance to and characteristics of the observer (Kroneisen 2018). Individual differences in how

one interprets a situation based on personality traits – in addition to contextual information – can increase sensitivity toward known deceivers. Bell et al. (2014) predicted that individuals with a stronger sense of morality adherence would be particularly attentive to those who violated social norms. It was also hypothesized that memory for an indiscretion would be magnified if it violated *self-related* interests to a greater degree than self-unrelated actions.

Using a variation of the common cheater recall paradigm (described above), participants were shown facial photographs while listening to descriptions that indicated either moral or immoral behaviors (morality) and a personal benefit or cost as a result of the behavior (personal consequences). For example, an immoral behavior associated with a benefit would be, “He lied to another person to sell that person your useless products.” A moral behavior associated with a cost may constitute, “He gave the promotion to another person rather than you because the other person was most qualified.”

Accurate recall of behavior morality was facilitated when the acts were described in terms of personal consequences. Specifically, immoral behaviors were particularly remembered when they were associated with a negative consequence to the observer, relative to a benefit. This suggests that human memory is particularly salient for acts that violate morality, as well as possessing a self-serving bias. Furthermore, individuals who demonstrated a strong sensitivity to acts of immorality were *more likely* to accurately recall the behaviors associated with immorality when a personal cost, as opposed to a benefit, was implied. An individual’s personal understanding and adherence to what is colloquially defined as socially acceptable and moral behavior can dictate the degree to which cheaters are recalled during social situations. Specifically, negatively viewed behaviors that also result in negative consequences are particularly salient.

Factors altering one’s perception of exploitation can also influence memory processing (Baumert et al. 2012). Individuals who display certain traits, such as a heightened fear of

exploitation toward trustworthiness (victim sensitivity), tend to show superior face memory for people with negative labels (Süssenhach et al. 2016). For example, a person who has been labeled as an untrustworthy cheater but behaves in an unexpectedly kind fashion tends to be well-remembered by those scoring high in victim sensitivity. In this case, the expectation for a socially deviant behavior to occur by a person in the focus of attention is violated, rather than confirmed, producing a memory advantage. However, persons labeled and expected to act in a positive fashion do not influence memorability for those high in victim sensitivity, regardless of their actual behaviors. The lack of differentiation in memory for those expected to act in a cooperative fashion is due to the hyper-focused attention on expected wrongdoers. Thus, an analysis of persons with such a personality trait suggests that information that is prioritized in memory with regard to the reputations of others is based on what is relevant and seemingly important information to the individual observer. This provides further support for a flexible reputational memory module that is context dependent and highly susceptible to unexpected information (Bell and Buchner 2012).

In addition to our personal beliefs influencing memory, how others are perceived has also been shown to markedly alter the degree to which others are remembered. The way a new situation is presented can frame the cognitive response that is made toward it. For example, memory is markedly improved for individuals displaying pro-social, cooperative behavior when the meeting context is prefaced with a description of a negative, aggressive neighborhood (Kroneisen et al. 2015). However, those without a preconceived knowledge to the characteristics of a neighborhood displayed a typical source memory advantage for aggressive persons. This suggests that an attunement toward threat bias may only occur when a negative context is not anticipated.

The enhanced memory for cooperative individuals, as compared to threatening individuals, appears to be in direct violation of a cheater detection module. Yet, both findings correspond with

the notion of a more flexible expectation violation advantage. When a negative expectation for behavior is given, positive behaviors are not expected. However, when no behavioral expectation is provided, we assume persons to behave in a cooperative fashion in accordance with social contract theory. This flexibility allows us to appropriately respond to any social situation, as opposed to an exclusive focus on negativity and avoiding deception by cheaters.

Conclusion

It is a common assumption in evolutionary psychology that modern functions of humans developed to serve an adaptive need. In the case of human memory, we tend to display a bias toward recalling information pertaining to cheating behavior. The unexpected and negative nature of such socially deviant actions violates the terms of social contract theory and could thus constitute a need for greater memory for such behaviors. However, a more critical analysis of the extant literature provides an alternative explanation: a more flexible and general notion of expectation violation within the social realm enhances memory recall (Bell and Buchner 2012). Information that is relevant to an observer and comes as a surprise within a given context can be an indicator that one's schema may not be valid. Although memory appears to prioritize cheaters, the additional effort and cognitive resources needed to understand such situations could account for this pattern of results.

Human memory is capable of honing-in on information that has been adaptively relevant and most informative in social interactions, with a particular devotion to understanding the unexpected. Because we tend to encounter individuals who are agreeable and cooperative, the unexpected and socially deviant tend to stand out in our mind. By adaptively focusing memory on the select cases in which behavior is inconsistent with our expectations, we are able to selectively mark such individuals as unique cases deserving of recollection.

Recessive Genes

Definition

Alleles that are not expressed phenotypically, or are only partially expressed, in the presence of other alleles.

Introduction

Scientists have been conscious of the detrimental consequences of inbreeding for nearly 150 years, in large part due to Darwin’s (1891) experimentation with plant species. Indeed, across multiple plant and animals species it has been observed that the offspring of closely related parents or “inbred” individuals are more likely to suffer deleterious genetic effects than their “outbred” conspecifics (Roff 1997). It has become increasingly clear since the discovery of Mendelian genetics that inbreeding depression is the product of homozygous recessive alleles (Charlesworth and Willis 2009). However, the precise impact of recessive genes and their role in inbreeding depression has only been brought to light in recent decades (Charlesworth and Charlesworth 1999).

Recessive and Dominant Genes

In diploid organisms such as humans (and most mammals), for any given gene one allele is inherited from each parent. In Mendelian traits, only one allele will be expressed at the phenotypic level. This allele is dominant, while the other allele is said to be recessive. Dominant alleles will produce the dominant phenotype when only one copy of the allele is present (e.g., in the case of heterozygosis). In contrast, recessive phenotypes

are only expressed when two copies of the recessive allele are inherited (i.e., homozygosis). This is referred to as complete dominance, wherein the phenotype of a heterozygous dominant is no different from a homozygous dominant. However, the relationship between genotypes and phenotype is frequently more complicated than that described by Mendel. In the case of partial dominance, the phenotype may resemble a point along a continuum from homozygote dominant to homozygous recessive. Importantly, because of mutation in the population, some alleles will have harmful effects and how these effects manifest will be influenced by patterns of recessive and dominant gene expression.

Directional Dominance

In most populations, harmful alleles generally exist at a low frequency and are maintained by mutation-selection balance. This is the balance between natural selection against deleterious alleles and processes that introduce them into the population (i.e., mutation). Dominant alleles that manifest in harmful phenotypes are likely to be eradicated by natural selection, due to their negative impact on fitness-relevant characteristics. However, those that are recessive are less likely to be purified by selection, as they are less likely to manifest in the phenotype. This means that deleterious alleles are more likely to be recessive than dominant, a phenomenon called directional dominance (Charlesworth and Willis 2009). When two related individuals produce offspring, the likelihood of harmful alleles being homozygous, and therefore expressed phenotypically, increases (Charlesworth and Willis 2009).

The probability of inheriting the same allele (i.e., autozygosity) from separate parents is referred to as the inbreeding coefficient. The relationship between inbreeding depression and the magnitude of the inbreeding coefficient has been demonstrated in many animals (DeRose and Roff 1999). Likewise, inbreeding depression has been observed in humans relating to the increased probability of a range of mental illnesses including schizophrenia and bipolar disorder as well as cancer and heart disease.

Recent advances in access to large-scale genotyping data have allowed researchers to quantify the more subtle effects of inbreeding depression in the general population. This is possible because all members of a species are “inbred” to the extent that they are all related to each other, and even comparatively small inbreeding coefficients can be associated with inbreeding depression. For example, Verweij et al. (2014) investigated the relationship between runs of homozygous recessive genes throughout sections of the genome likely to be identical by descent (i.e., autozygosity) and inbreeding depression in a range of fitness-relevant traits. Genotype data was collected from over 5,000 “unrelated” Finnish individuals and analyzed with reference to 18 traits including birth length, body mass index, height as an adult, blood pressure, heart rate, and other measures of health, as well as educational attainment and marital status. As predicted by inbreeding depression effects, individuals with more of their genome in runs of homozygosity were more likely to have traits associated with lower fitness, such as lower height, income, educational attainment, and grip strength, and higher physical and social Anhedonia.

Subsequent work has shown similar relationships between inbreeding depression and homozygosity using a massive cross-national sample of over 350,000 individuals from four continental groups (Joshi et al. 2015). Four complex, fitness-relevant traits (height, a measure of lung volume, general cognitive ability, and educational attainment) were all negatively associated with increased homozygosity, providing further evidence of directional dominance in humans.

Overdominance

To a lesser extent, inbreeding depression may also be the result of overdominance; a situation that arises when a heterozygote results in an exaggerated phenotype compared to either dominant or recessive homozygotes. This is also known as heterozygote advantage (Charlesworth and Willis 2009). A classic example of overdominance in humans is the case of sickle cell anemia. Sickle

cell anemia is caused by homozygosity of a single recessive hemoglobin gene, which leads to disorder of the oxygen-transport protein hemoglobin causing numerous health complications and reducing life expectancy to around 50 years. However, the gene also confers some protection from the malaria parasite. As a result, it was hypothesized that the gene may be maintained in higher frequencies in malaria-dense environments as heterozygotes would possess a single, harmless recessive gene, which nonetheless provided some protection against the parasite. Consequently, heterozygotes would be at a selection advantage over both dominant and recessive homozygotes, hence the term heterozygote advantage.

Until recently, sickle cell heterozygote advantage was primarily theoretical or estimated indirectly. Cohort studies have since enabled the direct observation of the protective effects of the sickle gene. Aidoo et al. (2002) collected data from a Kenyan birth cohort in a malaria-dense region and analyzed sickle cell traits as a risk factor for mortality. While no differences in all-cause mortality emerged before 2 months and after 16 months of age, between this time period heterozygosity was associated with a significant reduction in mortality. This was also the developmental period during which severe malarial anemia was more likely to occur, suggesting specific heterozygote advantage (Aidoo et al. 2002).

While evidence suggests that heterozygotes may be better off in certain environments, they also increase the likelihood of inbreeding depression. As a consequence of their genetic advantage, heterozygotes may be more likely to survive and reproduce, thus sheltering the recessive allele from purifying selection. As a consequence, the probability of homozygous recessive alleles and therefore inbreeding depression is increased in offspring of heterozygotes.

Conclusion

The importance of recessive genes should not be understated given their role in both classical and modern genetic models (Charlesworth and Willis

2009). By their nature, recessive genes tend to be shielded from purifying selection and have profound implications for an organism's fitness. Until recently, these mechanisms were primarily theoretical, but with the advent of more advanced technology, empirical approaches to both classical and nascent models will become more frequent and more important (e.g., Zietsch et al. 2014).

Reciprocal Altruism

Definition

Behavioral strategy where the actor incurs a cost and the recipient receives a benefit in terms of reproductive success, where the return benefit may be reciprocated at a later time.

Introduction

An unresolved issue with Darwin's Theory of Evolution by Natural Selection was altruistic behavior in nature. Unrelated individuals engaging in behavior where the actor incurs a cost, and the recipient a benefit (in terms of reproductive success), appears counterintuitive to evolutionary logic, where individual organisms are expected to engage in behaviors that directly increase survival and the probability of genetic representation in future generations.

Background

In 1964, WD Hamilton laid out the logic for altruism being selected for in related individuals, based on kin selection and inclusive fitness theory. Hamilton utilized evolutionary logic acting at the level of the gene, and mathematical modeling to explain how altruistic behavior could have evolved within populations based on their degree of relatedness.

Trivers' Model

Intrigued by the logic and determined to solve the evolutionary problem of altruism between unrelated individuals, in 1971, Robert Trivers introduced a theoretical model to account for the natural selection of altruistic behavior between unrelated individuals in the first of a series of revolutionary papers that laid the groundwork for modern evolutionary psychology.

Trivers identified ecological conditions favoring reciprocal altruism as an adaptive strategy, inducing unrelated individuals to cooperate in order to increase their own survival and reproductive success. Within a population, individuals must be long-lived, have low dispersal rates, and live in small, mutually dependent stable social groups with parental care. This ensures individuals have many opportunities for reciprocity with known individuals. Crucial to the system is that the inherent cost to the altruist be less than the benefit to the recipient, in terms of reproductive success, and that individuals monitor and keep track of these interactions. The evolution of cooperation and selection for pro-social behavior would be adaptive in such a system and would spread quickly.

Cheater Detection and the Evolution of Human Emotional Systems

One obvious problem was the potential benefits to individuals within the system who adopted a cheating strategy, where they take the benefits but refuse to reciprocate (actual costs and benefits of reciprocal altruism were later brilliantly demonstrated in vampire bats by Wilkinson in 1984). For the system to work, Trivers argued cheaters must be identified and discriminated against immediately. Individuals must refuse to engage with nonreciprocators, and eventually cheaters suffer greater costs than if they originally reciprocated. Trivers proposed reciprocal altruism as the basis for development of human emotional systems that evolved to mediate social relationships. Friendship, loyalty, fairness, justice, gratitude,

sympathy, empathy, moralistic aggression, guilt, regret, remorse, and compassion were put forth as behavioral strategies that evolved to effectively monitor and participate in complex social environments (Trivers 1985).

Conclusion

While Trivers (2002) acknowledges that he should have taken Hamilton's advice and left out the "maths" in the 1971 paper, and that cleaner fish and bird alarm calls are better examples of return-effect altruism, the overall importance of this paper cannot be overstated. The use of evolutionary logic to model and explain the most basic social behavior – cooperation – led to a massive intellectual movement, to not only reorganize and reexamine data on behavior in existing disciplines, but the creation of entirely new areas of inquiry, such as economic game theory (Trivers 2005).

Definition

Reciprocal altruism describes a situation in which an organism acts in a manner that temporarily reduces its fitness while increasing another organism's fitness. Underlying this behavior is the assumption that there is an ultimate fitness benefit based on an expectation that the other organism will act in a similar manner at a later time. It creates the obvious dilemma in which there is always a short-term benefit to cheating, which is why cooperating individuals must avoid being exploited by non-cooperating cheaters. Therefore, contingent cooperative investments that are based on the cooperative returns must be enforced through partner control and/or partner choice.

Introduction

It is relatively easy to explain altruism among relatives where kin selection causes genes to increase in frequency when the genetic

relatedness of a recipient to a donor multiplied by the benefit to the recipient exceeds the cost to the donor (Hamilton 1964; Carter 2014). How might an altruistic act be explained if the beneficiaries are not the organism's kin? Kinship selection works only when the individuals involved are closely related; it fails to explain the presence of altruism and cooperation between unrelated individuals, particularly across species. The theory of reciprocal altruism was originally developed by Trivers of Rutgers University in a landmark paper (1971) as an attempt to explain cases of (apparent) altruism among unrelated organisms, including different species. He argued that such altruism is advantageous to its practitioner if directed only toward those individuals who will reciprocate; given the right cost-benefit ratios, over time, each member of a reciprocal relationship will do better than by acting alone. As conceived by Trivers, reciprocal altruism is most likely to evolve in species with long lives, good memories, and viscous populations (those in which two individuals meet many times and remember each other's past behavior).

A major advancement of the theory of animal cooperation was the introduction of the concept of Prisoner's Dilemma. Initially invented in 1950 by Merrill Flood and Melvin Dresher who worked at the RAND company, the Prisoner's Dilemma was proposed as an instrument to model processes between conflict and cooperation and between selfishness and altruism. The Israeli mathematician Robert J. Aumann (1959) found that successful cooperation can emerge even between two competitors given they play a repeated Prisoner's Dilemma game called the "folk theorem." Aumann developed game theory with a special emphasis on the area of repeated games, the main topic for which Aumann was awarded the 2005 Nobel Memorial Prize in Economic Sciences. It was shown that if both players cooperate in the one-shot Prisoner's Dilemma, it is not a Nash equilibrium. For a game to be a Nash equilibrium, the number of interactions needs to be large or infinite. Anatol Rapoport, a Russian-born American mathematical psychologist, and his colleague Albert Chammah, a

Syrian-born American mathematical psychologist, further demonstrated the potential of the Prisoner's Dilemma when it is played repeatedly (1965). Trivers introduced the repeated Prisoner's Dilemma game to an analysis of animal behavior, and this Prisoner's Dilemma is known as the iterated Prisoner's Dilemma. However, it was not clear how to play the iterated Prisoner's Dilemma. The "folk theorem" did not define what is a good strategy here. Robert Axelrod, a political scientist from the University of Michigan, organized an unusual competition. He solicited computer programs containing different social strategies from other game theorists to be played against each other in repeated Prisoner's Dilemma tournaments. Across two tournaments, the winner was a short computer-based strategy submitted by Anatol Rapoport. This strategy is known as "tit-for-tat": it always cooperates on the first move and subsequently reciprocates what the social partner did on the previous move, betraying only when the partner betrays the cooperator. The development of the theory of reciprocity based on research of the Prisoner's Dilemma concept – the tit-for-tat and other strategies of cooperation and mechanisms of social control – has thrived since 1960s and 1970s. This has led to an important conclusion that social organisms use decision rules that are shaped by natural selection and that social processes can be expressed as mathematical equations and modeled with the help of evolutionary game theory.

Surprisingly, after hundreds of scientific papers published, the evolutionary and ecological importance of reciprocal altruism is still not clear, and there are serious questions arising on ecological/social/physiological conditions favorable for reciprocity to evolve. Evidence of reciprocal altruism in nonhuman species is largely denied based on, for example, an assumption that it requires sophisticated cognition. Although this restriction defines reciprocity out of existence, evidence shows that fungi, plants, fish, birds, rats, and primates enforce mutual benefit by contingently altering their cooperative investments based on the cooperative returns, just as predicted by the original

reciprocity theory. New evidence from vampire bats is of special interest because it shows that reciprocal exchange can indeed be more important for cooperation than relatedness (Carter and Wilkinson 2013, 2016). It is easy to understand skepticism related to the evolution of cooperation by reciprocity. Cooperation is costly to actors and beneficial to recipients; selection may favor cheaters accepting aid without reciprocation (Trivers 1971). However, reciprocity can generate evolutionarily stable cooperation if costly help sufficiently increases the likelihood that donors obtain fitness benefits in return for helping, provided that the benefits more than compensate for the costs of initial investment. This means that the benefit from being helped must on average exceed the cost of helping and that social interactions should be sufficiently frequent for social control to work (Taborsky 2013). This highlights the importance of considering information about the likelihood of getting adequate returns of any help provided to a social partner. Such information can be obtained from experience of previous interactions and can generate the following decision rules within evolutionary game theory: direct reciprocity (Axelrod and Hamilton 1981), indirect reciprocity (Nowak and Sigmund 1998; Rankin and Taborsky 2009), and network reciprocity (Nowak 2006) – the three directions which future research should focus on.

Prisoner's Dilemma

The Prisoner's Dilemma model shows how the rational pursuit of individual self-interest drives interacting organisms into an outcome that nobody prefers. To understand the Prisoner's Dilemma, one needs to imagine two partners in crime captured by police awaiting for a trial. Each person is faced with only two options: cooperating with the other one by refusing to confess or defecting from their criminal alliance by confessing. The prosecutor interrogates each crime partner separately and offers a deal to each person. If both cooperate by keeping silent, the

prosecutor cannot convict both partners of the more serious crime, and each criminal gets a light sentence (R, the reward for mutual cooperation). If one of them, the defector, incriminates the other partner, then the defector is rewarded with an even lighter sentence (T, the temptation to defect), while the other person gets the stiffest sentence (S, the sucker's payoff). If both partners defect each other, then each gets a lighter sentence than when only one goes for defection but still heavier than the sentence that each would have reaped from mutual cooperation (P, the punishment for defection). This is a nonzero game where all outcomes (T is the best; S is the worst) are relative and "my loss is not always your gain" as in a zero-sum game. This is because one partner can benefit without the other losing; they only need to cooperate. However, each prisoner has to make his decision without knowing what the other will do. In a non-repeated game, the prisoner should defect because defection pays better than cooperation. On the other hand, the dilemma has another solution given the social partners play the game repeatedly/indefinite number of times where "the future can cast a long shadow backwards onto the present," as noted by Robert Axelrod. The first experimental evidence of the iterated Prisoner's Dilemma in nature was presented by Manfred Milinski, the director of the Max Planck Institute for Evolutionary Biology in Germany (1987). Milinski studied the "predator inspection" in the three-spined sticklebacks (*Gasterosteus aculeatus*). This behavior is risky for the fish, but the information they obtain while inspecting an unknown object can benefit them. If the inspected is not a predator or it is not an active one, the group of sticklebacks does not need to move away. Milinski studied the behavior of sticklebacks when confronting a potential predator, because conflicts can arise within pairs of fish in these circumstances which resembled a series of games of Prisoner's Dilemma. Using a system of mirrors, Milinski provided single approaching a live predator with either a simulated cooperating partner or a simulated defecting companion. In both cases the test fish behaved according to tit-for-tat.

Tit-for-Tat and Related Strategies

Tit-for-tat won the famous Axelrod's tournament – a surprising outcome for such a simple strategy. Detailed analysis revealed that the simplicity accounted for the success of tit-for-tat either within the Prisoner's Dilemma game or in real-life situations. This is because a more complex strategy prevents the social partners from reading each other's intentions. Tit-for-tat has simple rules that are consistent and easy to figure out by the other player after a short set of interactions, thereby eliciting long-term cooperation (Axelrod 1984). Moreover, Axelrod found one more surprising property of tit-for-tat and other simple strategies such as tit for two tats submitted by John Maynard Smith, the British professor. The competition in each round of Axelrod's tournament became stronger as weaker computer programs were eliminated, while the remaining/dominating strategies were found to be all “nice” given they were also provokable – highly resistant against the occasional exploitation (Axelrod 1984). The property of being nice means never be the first to defect. Being nice is tightly linked to the property of “forgiving” because it only looks at the most recent move by the other player. All the rest of the history of interactions is not considered when deciding the current move, and this is why being nice and forgiving makes restoration of mutual cooperation possible.

Some other popular-related strategies are Pavlov, tit for two tats, generous tit-for-tat, contrite tit-for-tat, tit-for-tat empathic retaliator, and tit-for-tat sympathetic retaliator.

Pavlov (win-stay, lose-switch): Cooperates on the first move. If a reward or temptation payoff is received in the last round, then repeat the last choice; otherwise choose the opposite choice. It is relatively stable in a noisy environment. Similar to tit-for-tat but not forgiving, Pavlov will exploit altruistic strategies until it is punished by mutual defection (Kraines and Kraines 1989).

Tit for two tats: This strategy is same as tit-for-tat and cooperates on the first move. It is super forgiving and defects only when the opponent defects two times (Maynard Smith 1982).

Generous tit-for-tat: Similar to tit-for-tat, except that it cooperates with a probability q when the opponent defects (Komorita et al. 1968).

Contrite tit-for-tat: Same as tit-for-tat when an environment is not noisy and it is useful in a noisy environment. Social partners can be in good or bad standing: player A gets into bad standing if it defects when it should have cooperated. However, if A cooperates in the next round, it can restore its standing, and the pair (A, B) can recover from being stuck in mutual defection caused by a simple error in judgment or implementation (Sugden 1986).

Tit-for-tat empathic retaliator and tit-for-tat sympathetic retaliator strategies: Direct reciprocity is about repeated moves between a pair of social partners (Trivers 1971; Axelrod and Hamilton 1981), and indirect reciprocity deals with situations wherein cooperation is channeled toward the cooperative individuals within the group (Nowak and Sigmund 1998). Fishman (2006) considered the case of involuntary defection that is conceptually similar to an error in implementing a good intent, but in which case the reason for defection is the inability to cooperate given current circumstances. He concluded that the possibility of involuntary defection leads to the evolution of an “emphatic retaliator” but not of “sympathetic retaliator.” An emphatic retaliator is a rewording of contrite tit-for-tat, whereas the sympathetic retaliator differs from contrite tit-for-tat in which individual A refrains from punishing individual B after B has defected, if A assesses that B's defection was involuntary. However, “sympathetic retaliator” strategy has been recently found in nature where breeding birds used a tit-for-tat with an embedded “excuse principle” to forgive the neighbors that were perceived as unable to cooperate during mobbing of predators (Krams et al. 2013). The excuse principle dramatically increases the stability of tit-for-tat-like behavioral strategies within the Prisoner's Dilemma game and demonstrates the role of empathy in reciprocity since “sympathetic retaliator” strategy is also partially based on empathy.

Importantly, tit-for-tat's appetite for revenge proves self-destructive as it requires defection of a social partner even if the partner is unable to cooperate (Nowak 2006), while the "excuse principle" shows how this can be mitigated.

Direct Reciprocity

Briefly, direct reciprocity means that A helps B and B helps A. Direct reciprocity can be observed in cooperation between unrelated individuals or even between members of different species. Given that A and B can meet repeatedly during every encounter, each player has a choice between cooperation and defection. This game is known as the repeated/iterated Prisoner's Dilemma. The best strategy for playing the iterated Prisoner's Dilemma was found to be tit-for-tat. It is nice and never first to defect. Tit-for-tat is provokable: it returns defection for defection and cooperation for cooperation. It is not envious: it focuses on maximizing its own "score" instead of ensuring its own score is higher than that of the partner. Finally, tit-for-tat does not tend to be too clever because players need to figure out intentions of their partners. However, tit-for-tat is not resistant against mistakes which may cause the permanent breakdowns in cooperation. The substitutes of tit-for-tat, such as generous tit-for-tat and Pavlov strategy, are more flexible against defections and possible mistakes. Many other strategies have been suggested during recent decades, and the total number of these for the iterated Prisoner's Dilemma might even increase reflecting differences in the origin, evolutionary history, and ecological conditions of organisms under the study. Although strategies to reach reciprocity may be unlimited, Nowak (2006), a professor of Biology and Mathematics at Harvard University, proposes a general rule for direct reciprocity to become an important force in evolution of sociality: the probability w of another interaction between the same two unrelated players should exceed the cost (c)-to-benefit (b) ratio of the reciprocal act: $w > c/b$.

Indirect Reciprocity

Direct reciprocity is not capable of explaining many aspects of cooperation, especially when it comes to mechanisms for the evolution of cooperation in humans who often help strangers and donate to charities that never reciprocate back to the donors. Direct reciprocity needs the same individuals to meet again, while people often cooperate when they are not expected to see each other in the future. Some primitive forms of indirect reciprocity seem to be found in animals (Bshary and Gutter 2006). For example, Rutte and Taborsky (2007) of the University of Bern experimentally tested whether cooperative behavior of female wild-type Norway rats is influenced by prior receipt of help, irrespective of the identity of the partner. Rats that were trained in an instrumental cooperative task to pull a stick in order to produce food for a partner pulled more often for an unknown partner after they were helped than if they had not received help before. This reveals that nonhuman animals may show generalized reciprocity (Barta et al. 2011). However, this type of cooperation in full is a characteristic of human behavior only. Indirect reciprocity requires substantial cognitive demands because humans need to store in their memory information on hundreds and even thousands of other people and past interactions with those individuals and monitor information on interactions between members of our social networks. This often needs to be translated to/from other languages as a substantial part of our social information arrives from multiple often globalized channels. A good reputation is important, and humans take into account the possible consequences for their reputation before they decide to act. Theoretical and empirical studies of indirect reciprocity reveal that individuals who are more altruistic are more likely to gain reputation and receive help and other benefits (Leimar and Hammerstein 2001; Milinski et al. 2002; Fishman 2003; Hauser et al. 2003; Panchanathan and Boyd 2003; Nowak and Sigmund 2005). Several researchers have suggested that altruism is a costly signal of desirable qualities, which could have evolved by

sexual selection (McAndrew and Perilloux 2012). It has been recently shown that reciprocal altruism predicts mating success in humans so that altruists have higher mating success than non-altruists. This supports the idea that altruism is a sexually selected costly signal of difficult-to-observe qualities (Arnocky et al. 2016). The studies and calculations of indirect reciprocity may be complicated because humans often obscure their capabilities and reputation. Indirect reciprocity can lead to evolution of cooperation if the probability, q , of knowing someone's reputation exceeds the cost-to-benefit ratio of the altruistic act: $q > c/b$ (Nowak and Sigmund 1998).

Individual acts of indirect reciprocity may be classified as "upstream" or "downstream" (Nowak and Roch 2007). Upstream reciprocity is based on a recent positive experience which causes a person who receives a donation to feel motivated to act altruistically in turn. Individual A assists individual B, which then motivates individual B to help individual C. Downstream reciprocity is built on reputation, and it occurs when the performer of an act of altruism is more likely to be the recipient of a later act of altruism. In other words, A helps B, making it more likely that C will later help A.

Network Reciprocity

Network reciprocity is an interesting case of reciprocity which is based on the assumption that real populations are not well mixed and spatial structures of populations or social networks prevent individuals of random interactions. This means that some individuals may interact more often than others. Evolutionary graph theory is a useful approach to study such population effects (Lieberman et al. 2005). According to evolutionary graph theory, individuals occupy the vertices of a graph, and the edges determine who interacts with whom. Ohtsuki and coauthors (2006) show that if a cooperator pays a cost for each neighbor to receive a benefit, and defectors have no costs, and their neighbors receive no benefits, network reciprocity can favor cooperation. Research

shows that cooperators can prevail by forming network clusters, where they help each other. It has been suggested that the resulting "network reciprocity" is a generalization of "spatial reciprocity" (Nowak and May 1992).

Empathy-Altruism Hypothesis

Research in evolutionary biology has shown that altruistic behavior generally evolved for the return benefits it brings the actor. The empathy-altruism hypothesis by Daniel Batson and colleagues (Batson and Shaw 1991) postulates that for return benefits to play a motivational role in reciprocity or altruism, they need to be experienced by the social individual. Batson suggested empathy as the most potent candidate mechanism to underlie altruistic reactions in response to other individual's pain, need, or distress. The empathy-altruism hypothesis states that the decision of helping or not largely depends on whether the individual feels empathy for the person in need. Thus, altruistic behavior toward other including nonrelatives may be initiated when the individual feels empathy for another individual, that is, identifying with another individual and feeling and understanding what this individual is experiencing (Aronson et al. 1997; Gilovich et al. 2006; de Waal 2008). It is important to note that emotional response to another's suffering based on empathy has been shown to be different from aversive arousal or temporary depression-based egoistic responses to reduce aversive arousal or relieve negative emotions.

Empathy is a multifaceted phenomenon that is tightly linked to many psychological and physiological processes and thus provides a basis for other complex emotional and cognitive processes (Panksepp and Panksepp 2013; Palagi et al. 2014). Different levels of empathy are recognized according to neurobiological, psychological, and behavioral complexity (Hecht et al. 2012). The ability to react to the feelings of others appears early in life (Clay and de Waal 2013), and its neurobiological substrates have been documented in humans. Recently, it has

been shown that humans are instinctively prone to cooperate while selfishness comes with rational minds and experience that let people to decipher if they might occasionally gain more by acting selfishly (Rand et al. 2012; Jordan et al. 2016). Empathy is a well-documented phenomenon also in nonhuman primates (Palagi et al. 2014) and rodents (Langford et al. 2006; Bartal et al. 2011). Frans de Waal of Emory University, Atlanta, examines in *The Age of Empathy* (2010) how empathy comes naturally to a wide range of animals, including humans. Birds, for example, demonstrate some forms of reciprocal altruism while mobbing predators at nests of their nonrelative neighbors, a behavior which seems to be based on empathy (Krams et al. 2013).

Future research should test whether empathy is ubiquitous in cooperation and what is its role in shaping the decision rules and strategies of playing social games. It is also important to reveal physiological mechanisms of empathy. For example, recent research showed that reinforcement of adaptive social interactions in the brain requires coordinated activity of oxytocin and serotonin (Barraza and Zak 2009; Dölen et al. 2013) suggesting that important details of the mechanism of cooperation and reciprocity are still waiting to be revealed. Empathy might be also related to emotional disposition, i.e., tendencies to give, to cheat, and to respond to other's behaviors in which individuals significantly differ between each other, the evolution of which can be understood in terms of regulation of altruism as proposed by Trivers (1971).

Examples

Vampire Bats

Gerald Wilkinson of the University of Maryland showed that vampire bats (*Desmodus rotundus*) display reciprocal altruism (1980). The bats often feed each other by regurgitating blood. The bats only feed on blood and have to eat each second night – otherwise they will die. Therefore, food sharing is a great benefit to the receiver and a great

cost to the giver; food-sharing behavior was consequently explained in terms of direct reciprocity (Wilkinson 1984). It has been suggested that non-kin food sharing could have resulted from kin recognition errors, indiscriminate altruism within groups, or harassment. Gerald Carter and Gerald Wilkinson tested these alternatives and confirmed the role of reciprocity in the most excellent way (2013). Over a 2-year period, they fasted 20 individual vampire bats and induced food sharing on 48 days. It was found that donors initiated food sharing more often than recipients, a finding incompatible with the harassment hypothesis. Carter and Wilkinson found that food received was the best predictor of food given across dyads, and it was 8.5 times more important than relatedness of bats in dyads. Sixty-four percent of sharing dyads were unrelated. Consistent with social bonding, the food-sharing network was correlated with mutual allogrooming. Thus, these findings and past work published in 1980 in *Nature* support the hypothesis that food sharing in vampire bats provides mutual direct fitness benefits and can be explained in terms of direct reciprocity.

Primates

Grooming in primates can be explained as reciprocity (Stephens 1996) according to some studies. Robert Seyfarth and Dorothy Cheney (1984) found that in vervet monkeys (*Chlorocebus pygerythrus*) among unrelated individuals, grooming induces higher chances of attending to each other's calls for aid. However, vervet grooming behavior was also supported by kin selection because some part of this activity was observed between siblings (Lee 1987). Another study examined patterns of reciprocity in grooming among wild male chimpanzees (*Pan troglodytes*) where kin effects are negligible. It was found that some grooming was directed by lower- to higher-ranked individuals and that, on average, higher-ranked individuals groomed more reciprocally. However, reciprocity did not occur between

individuals close in their ranks. Thus, the results partly supported reciprocity and the current grooming trade within biological market model (Noë and Hammerstein 1994).

Mobbing Behavior and Nest Protection

Birds often help neighbors to defend their nests. Red-winged blackbirds (*Agelaius phoeniceus*), for instance, play a tit-for-tat strategy while helping their neighbors while mobbing nest predators (Olendorf et al. 2004). Additional experimental evidence has been obtained from mobbing behavior of the pied flycatcher (*Ficedula hypoleuca*). Krams et al. (2008) used stuffed owls to induce cooperative mobbing in triads of pied flycatcher mated pairs, with each triad consisting of three equidistant nest boxes (48–54 m apart) (A, B, and C). Pair A was exposed to a fake owl near their nest box to induce mobbing, pair B was held captive and prevented from mobbing, and pair C was left untreated, so that pair C always helped pair A with mobbing, but pair B could not. Pair B was released, and in 1 h pairs B and C were simultaneously presented with owls and tested at which nest box pair A would choose to assist during mobbing. In 30 of 32 trials, pair A assisted pair C. In an additional experiment, pair B was presented with an owl. In eight of nine trials, pair C, but not pair A, joined B in mobbing, as expected according to a tit-for-tat strategy. However, Russell and Wright (2008) objected that this strategy was cognitively unlikely for pied flycatchers. Connor (2010) stated that pair A did not assist pair B to avoid a potential parasite infestation. By showing that the degree of contingency was dependent on the costs and benefits, Krama et al. (2012) demonstrated in a follow-up experiment that reciprocal mobbing at nest boxes was not a by-product benefit. Subjects always helped neighbors mob regardless of past defections when nest boxes were placed only 20–24 m apart. This shows that when the predator is nearby, it is worth mobbing whether any benefit to others was incidental and not enforced. However, when the predator was farther away, the mobbing was more of a cooperative investment enforced by reciprocity. Therefore, reciprocity can involve both by-product mutualism benefits

and enforced benefits, while the difference between by-product mutualism and reciprocity is just the function of distance between the neighbors or the degree of perceived risk of predation.

Conclusion

Research on reciprocal altruism or reciprocity is an important part of modern evolutionary biology. Surprisingly, while mathematical part of research on reciprocal altruism may be viewed as extremely successful, there is less agreement about the importance of reciprocity for understanding interactions among nonrelatives and whether it occurs in nature at all. Indeed, experimental research on reciprocal altruism has so far received little attention, most likely because it is difficult to observe reciprocity in nature and to test its role and mechanisms within the framework of evolution of cooperative behavior. On the other hand, the most recent evidence from mobbing birds, Norway rats, and vampire bats indicates that reciprocal exchange can be more common in nature than previously thought and also more important for cooperation than relatedness, especially in social groups consisting mostly of non-kin members.

Reciprocal Altruism and Cooperation for Mutual Benefit

Definition

Cooperation is a behavior that is adaptive because it provides a benefit to another individual. Reciprocal altruism, or reciprocity, is cooperation that is conditional on receiving help from the recipient.

Introduction

How can “helpful” traits evolve when natural selection rewards selfish replicators? Generally speaking, the answer is through mutual benefit. If genes for a cooperative or “nice” behavior reduced reproduction of the individuals bearing them, those genes would eventually disappear. Thus, for cooperative behaviors to exist, cooperative genes must persist through *direct fitness benefits* to the individual cooperators or through *indirect fitness benefits* via relatives of the cooperator who share copies of those genes. Given this, cooperative traits can be explained by asking the question: *how does a cooperator’s genes benefit from its actions?* Below is an outline of the ways in which benefits arise from cooperation (see also West et al. 2007; Bshary and Bergmüller 2008).

Indirect Fitness Benefits or Kin Selection

Rather than fitness only being measured by an individual’s production of offspring, fitness

should also take into account gene propagation through other genetic relatives. Natural selection will therefore favor organisms that maximize their *inclusive fitness*, which takes into account *direct fitness* from direct reproduction and *indirect fitness* through assisting the reproductive success of genetic relatives (Hamilton 1964). Hamilton’s rule ($rB > C$), a formulation of *kin selection*, predicts that cooperation will occur if the net direct fitness cost of helping (C) is less than the benefit to the recipient’s direct fitness (B) scaled by the relatedness between the helper and recipient (r).

Direct Fitness Benefits

The Free-Rider Problem

The fundamental evolutionary problem for cooperation among non-kin is that free riders or “cheats” can often gain the benefits of cooperation without suffering the costs. The free-rider problem is often illustrated by thought experiments such as the “Tragedy of the Commons” and “Prisoner’s Dilemma.” The costs and benefits of actions in these thought experiments are analogous to the fitness costs and benefits that determine whether or not a heritable cooperative trait is stable over evolutionary time.

In the Tragedy of the Commons, several individuals share a public good, such as a shared pasture for grazing. Each rancher benefits from grazing the pasture, but the costs of grazing are shared by all. If one rancher restricts his grazing of the commons, other ranchers can graze the area that he attempted to conserve. The ranchers would gain the highest long-term gain if they all restricted their grazing, but each rancher’s highest short-term gain is to graze as much as possible. The result is a breakdown in cooperation and exploitation of the commons that hurts everyone, hence “Tragedy of the Commons.” If only each rancher could somehow ensure that others would also conserve the commons (and vice versa), then mutual cooperation would be easier. In the absence of such enforcement, free riders that exploit the commons take advantage of cooperators that conserve the commons. Without enforcement to prevent free riding, cooperation is

Reciprocal Altruism and Cooperation for Mutual Benefit, Table 1 Example payoff matrix for A given B’s decision

A’s payoff if	B conserves the commons	B exploits the commons
A conserves the commons	15 units for A	1 units for A
A exploits the commons ^a	20 units for A	5 units for A

^aRegardless of B’s decision, A’s highest payoff is to exploit the commons

unstable. When the payoffs for the Tragedy of the Commons exist for two players, it is called a “Prisoner’s Dilemma” (Axelrod and Hamilton 1981) (Table 1).

By-Product Mutualisms

One solution to the free-rider problem is when cheating is impossible. Consider a scenario where two hunters are needed to kill a large prey. If either hunter invests less in the effort, the prey will escape. This is an example of a *by-product mutualism*, when a behavior that is selfish benefits another individual as a by-product. Of note, if cooperative traits are defined as only those that are selected for due to their benefits to a recipient (West et al. 2007), then by-product mutualisms are not always considered cooperative.

By-product mutualisms can only occur when there is no opportunity for *cheating*. Hence, in these scenarios, the best strategy and the selfish strategy is to cooperate. In some cases, the benefits of cooperating are immediate, for example, when predators increase success by hunting in coordinated packs or animals reduce predation risk by grouping together. However, the same mechanism can operate over the long term with delayed benefits giving the impression of “altruistic” behavior, for example, when individuals aid the survival of group members because it inevitably helps their own reproduction or the survival of their offspring (*group augmentation*, Kokko et al. 2001). Models of by-product benefits can be lumped together (Davies et al. 2012) or further divided based on whether one actor invests in the other (pseudo-reciprocity; Bshary and Bergmüller 2008).

Direct and Indirect Reciprocity

If cheating is possible, stable mutual benefit requires enforcement to reward cooperation, punish cheating, or both (West et al. 2007). Enforcement mechanisms include *direct reciprocity* where individuals prefer to help those who help them in return (also called “reciprocal altruism” Trivers 1971; Axelrod and Hamilton 1981; Carter 2014), *indirect reciprocity* where individuals help those that help others (also called “reputation-based reciprocity,” Nowak and Sigmund 1998), or the direct *punishment* of free riders. These mechanisms lead individuals to either punish or avoid individuals that do not provide returns on a cooperative investment. Enforcement mechanisms can be further divided into partner control (reward and punishment of a single partner) and partner choice (switching or choosing among partners, *biological market theory*, Noë and Hammerstein 1994, 1995). Depending on the supply and demand of cooperative partners, potential partners might compete to be chosen. This outbidding leads to scenarios of asymmetric helping, where individuals invest more in high-value helpers, and the value of these helpers depends on their relative frequency in the population.

Enforcement of cooperation is clearly important for humans. Experimental demonstrations of enforcement mechanisms are also common for interspecific mutualisms among simple organisms like plants, fungi, and fish, but they are more difficult **to study** in animals like nonhuman primates, because long-term social relationships are difficult to **experimentally** manipulate (Carter 2014). There are therefore many cases of non-kin cooperation among long-lived social vertebrates where the evolutionary explanation remains ambiguous (Carter 2014; Wilkinson et al. 2016). Faced with such cases, authors often disagree on whether the null hypothesis should be that cheating is inherently impossible or possible but prevented by enforcement (Carter 2014).

Conclusions

All cooperative behaviors are mutually beneficial at the genetic level, in the sense that they

will not evolve unless the inclusive fitness benefits of being “altruistic” outweigh the costs. These benefits may accrue via a variety of mechanisms. Indeed, it is important to remember that different mechanisms, from kin selection to by-product benefits to conditional rewards to partner choice, can occur simultaneously. This makes it difficult to classify cooperative behaviors simply. However, all evolutionary explanations of cooperation must explain what prevents the free-rider problem, where cheats outbreed cooperators by gaining the reproductive benefits of cooperation without paying the costs.

Reciprocal Altruism and Group Living

Definition

Self-costly acts that confer benefits on others are reciprocated by the recipients such that a mutual benefit is gained. This reciprocal favoritism may be a mechanism relevant to the formation and persistence of group living.

Introduction

Group living is an elemental part of human life and is essential for the survival and replication of our species. Thanks to group living we have been more effective in hunting and protecting ourselves from predators through cooperation. One peculiar phenomenon observed in human group living is that individuals provide self-costly and seemingly altruistic benefits to other group members. For instance, someone might save a group member from drowning (benefit to the recipient) and thereby risking his/her own life (cost to the helper). Humans show such kind of behaviors even toward genetically unrelated others, such that inclusive fitness and kin selection (Hamilton 1964) cannot account for it. This kind of behavior

can be explained by reciprocal altruism, which may have played an important role in the evolution of human group living.

Reciprocal Altruism

In 1971, Trivers published his paper on reciprocal altruism where he explained how and why even nongenetically related individuals perform seemingly altruistic acts toward each other. He argued that natural selection favors performing altruistic acts as long as these acts are reciprocated and result in a net benefit for each of the involved parties. For instance, helping someone from drowning makes sense as long as this person reciprocates by performing a similar act of altruism at some point in the future (actor-reactor reciprocation). A considerable amount of research and theorizing has since been done that builds further on the ideas first posed by Trivers (1971).

One of the most influential papers was published by Axelrod and Hamilton (1981), which showed that in a repeated prisoner's dilemma (PD) game reciprocal altruism can emerge as an effective strategy. The PD game is a 2-player game in which one can either cooperate or defect (not cooperate). In this game mutual cooperation leads to the highest joint outcome (i.e., an altruistic act of both players), mutual defection leads to the lowest joint outcome (i.e., no altruistic act of both players), and if one player cooperates and the other defects, the cooperator will get the lowest possible outcome and the defector the highest possible outcome (i.e., an altruistic act of one player that is exploited by the other player). By letting different playing strategies compete against each other, Axelrod and Hamilton (1981) showed that a "tit-for-tat" strategy (suggested by Anatol Rapoport), in which one always starts with cooperation and then reciprocates the decision of the other player, is particularly effective. This can be seen as a demonstration of how reciprocal altruism may evolve, although it has been criticized for its appropriateness as a model of reciprocal altruism (for a discussion, see Boyd 1988).

Given that the standard repeated PD game is an oversimplification of real-life social interactions, others have since looked at additional factors that are often present in real life but ignored in the standard repeated PD game. For instance, it has been shown that forgiveness – modeled with a “generous tit-for-tat” strategy that proceeds cooperating despite facing defection some of the time – plays an important role in maintaining reciprocal relationships when the environment is noisy or error-prone (Nowak and Sigmund 1992).

One problem that arises when people perform reciprocal altruism is that it allows the recipient of the altruistic act to defect (not reciprocate), also known as cheating. Trivers (1971) already pointed out that a “complex, regulating system” must have evolved in order to detect or prevent cheating. For instance, it has been suggested that humans have developed adaptations to help recognize cheaters (Cosmides and Tooby 1992) and might use strategies like “raise the stakes,” in which one slowly increases the magnitude of the altruistic acts when it is reciprocated, so that the negative consequences of cheating by unknown interaction partners are minimized. Given that individuals are able to identify and distinguish cooperators and non-cooperators with whom they did not have prior interactions (e.g., by “cues” of an individual’s reputation), cooperators are able to help each other indirectly (i.e., indirect reciprocity; Nowak and Sigmund 1998).

The term reciprocal altruism has been criticized since its long-term consequences lead to a mutual benefit, therefore indicating that reciprocity actually does not involve individual costs, as it would be the case in “pure” (strong) altruism. Alternative terms that avoid this semantic problem are “reciprocity” or “reciprocal cooperation.”

Conclusion

There is convincing evidence that reciprocal altruism is an important predictor of human

cooperation. Yamagishi and colleagues have formulated the theory of bounded generalized reciprocity to describe how expectations of (direct or indirect) reciprocity account for behavior within and between groups. They argue that individuals expect greater reciprocity from in-group than from out-group members and that this in turn not only leads to within-group cooperation but also to in-group biased perceptions and behaviors (for a summary, see Yamagishi et al. 1999). Hence, reciprocal altruism may be an important mechanism for the formation, functioning, growth, and persistence of groups. For cooperation to remain in increasing group sizes, however, additional supportive mechanisms are required, e.g., retribution systems. Moreover, reciprocal altruism may also lead to the emergence of strong reciprocity among group members through group selection (Gintis 2000).

Reconciliation

Zoe Johnson-Ulrich
Oakland University, Rochester, MI, USA

Synonyms

Definition

Affiliative behaviors between a victim and an aggressor after a conflict (Emery et al. 2007).

Introduction

Reconciliation has not been observed in any corvids at this point. However, a related behavior, third-party post-conflict affiliation (also called consolation), is common in both rooks and ravens (Emery et al. 2007; Fraser and Bugnyar 2010, 2012; Seed et al. 2007).

Consolation

For rooks, consolation occurs as an affiliative behavior between a victim (or aggressor) and its partner, and it might reduce stress and strengthen alliances (Emery et al. 2007) (see the Social Systems subheading under the ► [Corvids](#) entry for information about affiliative behaviors in rooks and ravens). In particular for rooks, bill twining behavior appears between partners within a minute after a fight and almost exclusively in this context (Emery et al. 2007). Seed et al. (2007) discuss how consolation, but not reconciliation, makes sense in the context of the social system of rooks and matches what is seen in similar social system in primates. Rooks only form strong partnerships with one other rook, so there is no benefit to reconciling a “non-valuable” relationship, but there is a benefit in increasing the bond with one’s partner (Seed et al. 2007). Given that affiliative behaviors are often reciprocal, this could form a foundation for morals around exchange, as in humans (e.g., Stevens and Hauser 2004), but there are no reports of rooks punishing other rooks if affiliative behaviors are not reciprocated (Emery et al. 2007; Scheid et al. 2008; Seed et al. 2007), and indeed this kind of behavior is rare across all animal species (de Waal and Brosnan 2006; Stevens 2004; but see Bshary and Grutter 2005).

Ravens show consolation via affiliative behaviors toward other ravens that they associate with (not just mated partners), particularly those that they have a valuable relationship with (Fraser and

Bugnyar 2010, 2012). Consolation behaviors are correlated with social support (i.e., aiding another raven in an aggressive encounter); this social support is mostly given to aggressors in conflicts but also to victims (Fraser and Bugnyar 2012). Ravens are more likely to support group members that are dominant to them, suggesting that it functions to reinforce good relationships within groups of ravens, but they also supported kin and those who preened them (Fraser and Bugnyar 2012). There is no evidence that social support was reciprocal, so it seems to have more long-term functions relating to relationship stability within groups (Fraser and Bugnyar 2012).

Conclusion

Corvids do not show reconciliation, but they do show “consolation,” also known as “third-party post-conflict affiliation” in which a corvid will display affiliative behaviors toward a partner that had recently engaged in a conflict, either as the victim or the aggressor.

Definition

The Red Queen hypothesis is an evolutionary hypothesis that states that all living beings

must constantly adjust, evolve, and reproduce while attempting to survive ever-evolving predators.

Introduction

This hypothesis was first proposed by Leigh Van Valen in 1973. The term “Red Queen” is a reference to a statement made by the Red Queen to Alice, characters in the popular 1871 novel *Through the Looking-Glass*, written by Lewis Carol.

The Red Queen Hypothesis and its Relevance

The statement that sparked this hypothesis is “Now, *here*, you see, it takes all the running you can do, to keep in the same place” (Carroll 1871). Van Valen's reference is essentially a metaphor for an evolutionary arms race. Predators that undergo a beneficial adaption may spark a change in selection pressure when it comes to a group of prey. This, in turn, would continue in a positive feedback loop, which gives rise to a form of antagonistic coevolution. Predators must attempt to compensate for better defensive adaptations that are being used by prey. For example, rabbits are considered prey, and foxes are considered predators. In this example, the only way the foxes can compensate for a better defensive adaption by the prey (e.g., rabbits are able to run faster than their parents) would be to adapt a better offensive adaption (e.g., foxes are able to run faster than their parents) (Vermeij 1987).

Further, the Red Queen hypothesis has other practical applications to humans outside of the predator/prey model. According to military researcher Azar Gat, evolutionary theory and the Red Queen hypothesis are instrumental in understanding some of the many aspects that can contribute to war. Gat states “The Red Queen effect arises when two competing groups find themselves in a security dilemma. The security dilemma results when a group takes defensive

measures (which possess inherent offensive capabilities) to improve their security, triggering a military arms race. This arms race, much like the example previously referenced, causes each side to consume ever increasing amounts of resources in order to outpace the other and to gain an advantage” (Gat 2009). An example of this occurrence was the nuclear arms race between the United States and the Soviet Union which began in 1945 and ended with the signature of the START I treaty in 1991. It is easy to see where the parallels exist between the evolutionary theory and the real-world application of this hypothesis.

Conclusion

In conclusion, the Red Queen hypothesis is rooted within evolutionary theory; however, it transcends theory and is able to be represented by several aspects of modern society, including war.

Low SES. Socioeconomic status (SES) refers to a person's income, education, and occupation, some combination of which determines her overall social standing. The relevant markers of social standing will vary across communities and cultures, but researchers afford these three variables special attention given their centrality to the increasingly global market system. A person with low SES will rank toward the bottom of their community's income, education, and/or occupational prestige distributions.

Economic Redistribution. Although seemingly straightforward, economic redistribution – altering the prevailing allocation of some economic good or token among a population – is a

dangerously vague term, open to political exploitation, and the root of much jumbled thinking. Take, for example, the 2003 Bush tax cuts, which experts and most Americans recognized as a massive transfer of wealth from the poor to the rich. It was an economic redistribution, but not of the kind people usually mean when they talk about such efforts. Even if we limit the definition to those undertakings that give *from* them-that-have *to* them-that-don't (as is the case in this entry), we are still a long way from covering our bases. Private charitable donations and centrally run progressive tax schemes are worlds apart on the political spectrum and require totally different justifications and institutions. Experimentalists often record voluntary transfers of money between subjects, whereas public opinion scholars (on whose work we focus here) tend to measure survey respondents' self-reported attitudes toward government programs and tax policies. There are occasions when discussing economic redistribution *broadly* is reasonable, even preferable (review articles with strict word limits among them), but this should be done with great care in academic and policy settings. Whenever possible, specify: Redistribution of what, among whom and along what lines, facilitated how?

Introduction

Socioeconomic status has a clear-cut but surprisingly subdued relationship with redistributive preferences. Supporting economic redistribution stands to directly benefit people of low SES, and low SES individuals are empirically more supportive of and more likely to participate in redistributive measures, but not to the extent that most researchers would expect.

The Influence of SES on Redistributive Preferences

Individuals with less money, less education, and less work have clear incentives to be, and statistically are, more favorable toward redistributive efforts than those with more. Tied up with each

SES component are perceptions of socioeconomic mobility – the timing and apparent flexibility of SES. See Alesina and Giuliano (2011) for an extended introduction to the information provided in this section.

Income

The more money you take in, the less you support economic redistribution. (The language associated with income acquisition is tricky. I say 'take in' here because *earn* implies that wages are proportional to merit and secured through direct action on the part of the employee, and that automatically imbues the transaction with a moral quality. Such words identify the income as deserved *prima facie*, and that can influence people's willingness to redistribute it.) Income is a statistically dependable predictor of redistributive preferences and behavior, and its substantive influence is on par with that of education.

Education

The amount and pedigree of schooling serve simultaneously as markers of social prestige and determinants of economic mobility. In this light it is unsurprising that, all else equal, individuals with more formal education are consistently more opposed to economic redistribution. If schooling is (in part) an investment in future consumption, individuals making that investment will not want to part with its dividends. (This is not to say that all people are equally able to invest in their educations.) But this finding flies in the face of the popular conception of the socially progressive by-products of higher education. That is because schooling and ideology have an *interactive* relationship when it comes to redistribution, whereby "the effect of education reinforces that of political orientation" (Alesina and Giuliano 2011, p. 107). More years of schooling make self-identified left-wingers more supportive of redistribution, but taken by itself, education promises future economic and social prospects and therefore a disincentive to redistribute.

Employment

Unemployed individuals are more open to redistribution than are their employed compatriots,

though this relationship does not consistently achieve statistical significance. There is evidence that the American unemployed feel less defined by or trapped in their unemployment compared to the out-of-work in other nations, where unemployment can be a more dependable prognosticator of policy preferences. More reliably associated with support for redistribution is a *history* of unemployment and personal traumas of the kind that cause or directly result from trying financial situations, although the magnitudes of these explanatory variables are relatively meager. Individuals who experience and remember such negative shocks appear to learn from their ordeals, tempering their optimism about upward socioeconomic mobility and lessening their aversion to wealth reallocation in case the dice ever again roll against their favor.

Perceived Mobility and Personal Narrative

Personal SES trajectory is a double-edged sword. Whereas experiences earning a low income, being unemployed, and undergoing financial trauma as an adult induce an individual to favor redistribution, growing up in a family that experienced such trials may encourage a person to *disfavor* redistribution if they are relatively better off now. For example, individuals who enjoy higher occupational prestige than their parents are prone to oppose redistribution. The most prevalent explanation for this and related findings is that people who outpace the SES into which they were born are optimistic about upward socioeconomic mobility and will not want to threaten potential future economic gains by backing redistribution in the present. In addition to this strategic positioning, it may also be that someone who came from a low-SES household is invested in maintaining – both internally and in public – a personal narrative in which they overcame adversity and are therefore less willing to part with their hard-fought gains. That is, they may feel (and may need to feel) especially *deserving* of their improved SES and its attending financial benefits, and are therefore less willing to part with them (more on this later).

Explaining SES's Subdued Influence on Redistribution

While theoretically and statistically solid, the substantive connection between SES and distributive preferences is perplexingly meager. For example, a majority of the American poor deem the prevailing economic system “basically fair” (Jost et al. 2003) and back what they know to be self-harming, regressive economic policies (Bartels 2008). Why don't low-SES individuals support redistribution more vigorously and in greater numbers? There are several contending explanations, all of which need to better account for one another. See Bower-Bir (2014, appendix B) for an extended overview of prevailing explanations.

Greed and Optimism

The chattering class's favorite explanation holds that people on the lower rungs oppose shortening the socioeconomic ladder because they are confident that they will eventually climb it. That optimism, however, is neither excessive nor does it extend far into the future. Low-SES Americans, for example, have more-or-less reasonable definitions of and expectations regarding personal income and wealth. More to the point, they are not overly concerned with achieving wealth, focusing instead on financial stability. And however sanguine they are about their own financial futures, they are not overly so about their children's.

Neoliberal Intellection

Some economists posit that low-SES redistributive skepticism is farsighted. In wanting to grow the economic pie and their (relatively slender) slice of it, low-SES individuals may shun redistributive measures for fear they generate disincentives to work, save, and invest. This stance would be personally uncomfortable in the short term but might lead to widespread, long-term gains for everyone. But not only are such neoclassical arguments generally unpopular among low-SES populations, people of all socioeconomic backgrounds are decidedly myopic in appraising economic policies (Page and Shapiro 1992; Bartels 2008).

Confusion

Rather than economically, political scientists fear that the poor think incoherently. Scarcity of key dietary, social, and economic resources can temporarily, and in some cases permanently, impair a person's cognitive abilities (Mullainathan and Shafir 2013). Add to that redistribution's complexity, especially at the policy level where tax and welfare laws are negotiated outside of the public's view and in highly technically language. Low-SES citizens may not fully grasp issues like tax incidence, and their policy preferences are backward because of it. Moreover, low-SES populations may be hoodwinked into supporting regressive, self-detrimental policies through targeted, prolonged political and media promotions (Bartels 2008; Page and Shapiro 1992). Although powerful forces, ignorance and manipulation do not entirely account for people's puzzling redistribution preferences (Lupia et al. 2006).

Delusion

An influential set of psychological models known as "just world" or "system justification" theories postulate an automatic and near-universal human need to believe in the fairness of outcomes and/or processes: that people get what they deserve and vice versa. The basic notion is that "living in an unpredictable, uncontrollable, and capriciously unjust world would be unbearably threatening, and so we cling defensively to the illusion that the world is a just place" (Jost et al. 2003, p. 58). This reaction is apparently facilitated through conscious and non-conscious means and may persist whether the mentally insufferable transgression is directed at one's self or others.

Natural Justice

Combining insights from institutional economics and moral philosophy, researchers who study justice as a natural phenomenon find that people will tolerate psychologically troubling and financially detrimental economic distributions if they judge those distributions *deserved* (Bower-Bir 2014). Indeed, redistribution in such cases would be unjust, taking from the deserving and giving to the undeserving. People are not preoccupied with

justice because they are moral, *per se*, but because moral concepts like economic justice and deservingness are *social institutions*, (Binmore 2011) and violating institutional boundaries is expensive, inviting internally and externally inflicted costs such as guilt and ostracism. Rather than the universal, intuitive definition of fairness that psychologists often seek (e.g., Starmans et al. 2017), natural justice scholars treat desert as *emergent*, fashioned over repeated interactions among humans trying to allocate all manner of goods, treatments, and duties. Definitions of desert vary across communities and resources, but often with common elements. An individual's willingness to redistribute, then, depends on her definition of economic desert – which may preclude specific redistributive avenues – and the degree to which she thinks economic desert is currently rewarded (Bower-Bir 2014).

Conclusion

The above-detailed approaches likely complement one another, applying to specific situations and populations. Multiple researchers conclude, for example, that individuals must perceive inequality as undeserved before they are willing to combat it (e.g., Bower-Bir 2014; Starmans et al. 2017). The next question is not whether but *when* and *for whom* is this willingness driven by socially evolved norms, as the natural justice contingent contends, and when is it driven by a deep-seated aversion to inborn conceptions of injustice, as psychologists posit? Similarly, rather than wonder at and bemoan citizen ignorance and delusion, political scientists might uncover specific aspects of redistributive policy that confuse and frighten people. People of all backgrounds respond to social, psychological, and personal pressures, and plenty of parties peddle economic ignorance and fantasy. Rather than focusing on one angle of attack, researchers must cross disciplines to fully rectify the straightforward but empirically muted support for economic redistribution among the lower socioeconomic strata.

Finally, a warning: The theories introduced in this article use ancient and nuanced terms like

justice, fairness, and desert, often cavalierly. (For a preliminary untangling of these closely related terms, see Bower-Bir (2014, Chap. 2). Briefly, justice is getting what one deserves. Desert is the meriting of some treatment or resource, and the concept itself bridges the myriad and otherwise isolated notions of fairness.) Scholars from all disciplines are guilty, but those from the brain sciences – in their quest to uncover innate moral principles – are especially susceptible. For example, psychologists Starmans et al. (2017) acknowledge that their predecessors speciously equate *just* and *equal* outcomes, only to themselves conflate *fair* and *equitable* processes, the latter being one of many possible flavors of the former. Similarly, neuroscientists Decety et al. (2015) tacitly advance a definition of *just* behavior as *altruistic* behavior. Take care not to overreach, believing your favored definition of a moral concept to be *the* definition of that concept. Social scientists ignore one another and moral philosophers at their own peril (Binmore 2011).

Thermoregulation

Definition

Thermoregulation is the maintenance of a relatively constant core body temperature that in humans is about 37 °C. Although there are normal fluctuations that occur during the day (circadian rhythm), month (menstrual cycle), and throughout the lifetime (aging), the maintenance of this temperature via physiological homeostasis is critical to human survival. The hypothalamus is the central integration center for thermoregulation (Tansey and Johnson 2015).

Introduction

Humans are homeothermic animals, which involve the pursuit of a homogeneous state for its thermodynamic temperatures and thermal inertia and the ability to adapt to fluctuation in the environment (Fig. 1) (Garcia-Falgueras 2017). However, in contemporary society, some humans have become too sedentary and physiologically unresponsive to the extent that some individuals might now require thermal therapeutic intervention for the lack of exercise or thermostatic

Regulation of Body Temperature, Fig. 1 Schematic representation of the human body with differences in color for temperatures. It is noticeable how in cold states (figure on the left) upper and lower extremities (i.e., hands and feet) are the first to get colder (color blue)

perturbations in their daily life (Tipton 2019). Both hot and cold water exposures have been reported to improve health and mood states (Naumann et al. 2017; Van Tulleken et al. 2018).

Autonomic hypothalamic disorders are accompanied by hypothermia. A case was described of a patient who, after a head injury, was unable to maintain core temperature during cold stress, unless he was capable of normal perspiration (for revision see Swaab 2004). Climacteric hot flushes are sudden vasodilatation episodes of the facial and upper abdominal skin, and they are accompanied by increased levels of luteinizing hormone (LH) and luteinizing hormone-releasing hormone (LHRH). Men with testicular insufficiency and woman after hypophysectomy also experience hot flushes (for revision see Swaab 2003).

The hypothalamus is composed of several nuclei populations interconnected to each other and to other brain areas, regulating the peripheral energy balance and expenditure. This process is controlled by the arcuate nucleus in the hypothalamus, the superior periaqueductal gray matter, the nucleus of the solitary tract structures, and the nucleus of superior septal area, via a multi-signaling cascade which includes GABAergic receptors, neuropeptide Y (NPY), leptin, insulin, agouti-related protein (AgRP), proopiomelanocortin

(POMC) neurons, orexin (OX), and other factors (Contreras et al. 2017; Griffin et al. 2001). They are released when the intestine detects the presence of nutrients, and they help to promote the feeling of satiation suppressing the behavior of eating or food intake (Hopkins and Blundell 2016). Norepinephrine is also involved in regulation of body temperature changes, and somatostatin from the periventricular nucleus potentiates the thyroid-stimulating hormone (TSH) response to cold in experimental animals (Swaab 2003, 2004).

The brain has specific neurons sensitive to temperature. In 2 μ m coronal tissue slices of rat preoptic area of the hypothalamus, it was described that different dendritic organizations exist depending on physiological characteristics: warm-sensitive neurons (receiving afferent input from spinal and skin-cutaneous thermal receptors) have a perpendicular orientation for its dendrites, whereas temperature-insensitive neurons are parallel to the third ventricle (Griffin et al. 2001).

Depression is one of the most common neuropsychiatric diseases, with sadness often being associated with the feeling of cold and the blue colors. Loneliness, marginalization, or isolated extreme states are also linked to cold and sadness. However, one-third of depressive patients fail to respond to conventional antidepressant medication. It is interesting that hyperthermic baths (water at 40 °C during 30 min) have recently been demonstrated in a pilot study to have a positive and consistent effect on mood, sleep quality, and treating severe depressive symptoms (Naumann et al. 2017).

Gender Differences in Human Thermoregulation

Structural differences between men and women have been found to relate to sweating or perspiration, but no substantial distinctions about effectiveness in thermoregulation were reported (Kaciuba-Uscilko and Gruzca 2001). A strategy for thermoregulation that implies evaporative cooling (sweating in humans, panting in dogs, salivation

in rodents) increases the heat loss (Morrison 2016) and is different among genders. Body size and surface area, adiposity, body mass and composition, working capacity or resting metabolic rates, and hormonal fluctuations in woman or menopause might all partly contribute to the overall thermal responses explaining those sex differences in thermoregulation. However, further studies would be necessary to tease these effects apart beyond (Kaciuba-Uscilko and Gruzca 2001).

The thyroid hormones (THs) in the brain act in the hypothalamus and its ventromedial nucleus to modulate energy balance. Central triiodothyronine (T3) regulates hepatic metabolism through the vagus nerve and brain adipose tissue (BAT) which increases lipid oxidation and thermogenesis in the whole-body level for central T3 and peripheral glucose homeostasis (Martínez-Sánchez et al. 2017). When patients present a thyroid dysfunction, hyperphagia is occurring, whereas weight loss is often found with hyperthyroidism (Martínez-Sánchez et al. 2017).

On the other hand, acute differences in temperature responses between men and women were measured, and they found in an experiment the existence of the difference related to sudomotor functions and skin blood flow, because of sex hormones or osmolality. But they did find no differences related to physical characteristics, for example, to the relative onset threshold of sweat production, but related to physiological functions, suggesting solid gender differences: women had a lower whole-body evaporative heat loss, higher requirements for heat loss employed, and bigger local sweat rate compared to men (Gagnon and Kenny 2012). It has been experimentally demonstrated that men and women respond differently to the same low temperatures: women feel less comfortable, feel colder by losing heat, and start shivering earlier as an indicator of cold stress to heat production, compared to men (Kaikaew et al. 2018).

During the lifespan differences in thermoregulation also occur: hot flushes affect millions of individuals, but the mechanism is not fully understood (Rance et al. 2013). Skin thermal afferent input reaches the hypothalamus

(preoptic, dorsomedial areas, and arcuate nucleus) to inhibit warm-sensitive output neurons (Morrison 2016). The hypothalamus plays an important role for this temperature process (regulation of systemic energy balance by regulation feeding behavior and energy expenditure), with dynorphin, LH and gonadotropin-releasing hormone (GnRH) neurons, and estrogen receptors being involved (Martínez-Sánchez et al. 2017; Rance et al. 2013).

Estradiol acts upon the ventromedial hypothalamus of rats and regulates brown fat thermogenesis and energy balance (González-García et al. 2018). The lateral and ventromedial hypothalamus regulates the thermogenesis and energy balance via brown adipose tissue and browning (described in the next section) of white adipose tissue (Contreras et al. 2017). Moreover, a wide array of nonthermal physiological parameters, disease processes, neurochemicals, or drugs can influence the natural circuit of thermoregulation (Morrison 2016).

Body Temperature in Obesity

There is a reciprocal and metabolic relationship between energy intake and energy expenditure, occurring in the hypothalamus as the calorimetric satiety center which regulates lipostasis (Hopkins and Blundell 2016) (Fig. 2). Brown adipose tissue in infants is located in the interscapular region and plays an important role in thermogenesis. This brown fat was thought to happen mainly in defenseless creatures (small mammals and human infants) exposed to hypothermia and to regress by adulthood, but brown fat tissue was “rediscovered” in adult humans, and it is activated robustly by cold (Cohen and Spiegelman 2015). Some investigators have suggested exposure to cold (19 °C for 2 h daily) might result in weight lost for brown and beige fat activation (Cohen and Spiegelman 2015).

A lower core body temperature has been suggested as a predisposing factor toward obesity; however, no general differences in the core body temperature were found between normal weight

Regulation of Body Temperature, Fig. 2 Thermographic picture of a sportive and thin person playing tennis. The image, taken with a special camera, shows how temperatures vary in different surfaces of the tennis player's body depending on the wavelengths

and obese individuals (Heikens et al. 2011). In a study performed on mice, a sex difference was found in their brains and saturated fatty acids, but not in plasma-free fatty acids. Male mice had an increase of saturated fatty acids (30%), while the amount of oleic acid and docosahexaenoic acid (DHA) was higher in female mice (Rodríguez-Navas et al. 2016).

Conclusion

Thermoregulation is the maintenance of a relative normal body temperature through fluctuations of temperature that occur during day (circadian rhythm), month (menstrual cycle), year (different seasons), and throughout the lifetime (aging). It occurs via physiological homeostasis regulated in the hypothalamus; it is critical to human survival. Body weight and energy consumption, expenditure, as well as feeding and satiation behavior are mainly regulated in the brain. Brown and beige fat seem to have therapeutical effects over body energy and its metabolism, while sex differences have been found in sweat, in adaptability to cold environments, and in brain-saturated fatty acids, but not in the plasma-free fatty acids.

Definition

A theory from Karl Bogislaus Reichert and Ernst Gaupp regarding the homology of incus and malleus, with the quadrate and articular, respectively.

Introduction

Reichert and Gaupp's theory is credited for their thesis that mammalian middle ossicles are derivatives of the reptilian jaw bones. Despite some opposition to this theory, the contribution to the scientific knowledge is widely accepted.

What the Theory Postulates

This theory was firstly established by Karl Bogislaus Reichert (see Reichert's cartilage) and then further elaborated by Ernst Gaupp, founder of modern studies in craniogenesis. The theory is regarding the origin of the mammalian ossicles of the ear and the relationship between the reptilian jaw bones and mammalian middle ear bones in 1837 (World Heritage Encyclopedia 2017).

Specifically, the theory posits that the malleus and incus are the evolutionary products of the first pharyngeal arches of the skeletal features of the middle ear (Takechi and Shigeru 2010). Together with the stapes, without the dermal component called the goniale of Gaupp, it is suggested by Westoll (1944) to be homologous to the reptilian conumella auris, quadrate, and articular. Interestingly, the theory proposed by Reichert and Gaupp was established before Darwin's *Origins of Species* (Takechi and Shigeru 2010).

Modern histological developments have shown that the incus was developed from the posterior part of the palatoquadrate as a primordium associated with the basal part of the ascending process of the palatoquadrate by a fiber of connective tissue, therefore confirming Reichert's theory (Takechi and Shigeru 2010). Similarly, Reichert-Gaupp theory is supported based on molecular genetic evidence which supports the serial homology representation of the visceral arches (Prince and Hunter 2002).

There have been, however, other theories opposing Reichert's theory. Hanson et al. (1962) posited that the first and second arch contributed to the middle ear ossicles; Otto (1984) emphasized that human congenital abnormalities showed that the development of jaw and middle ear development are not related to each other and that the malleus and incus were derived from the extracolumella. Jarvik (1980, as cited in Takechi and Shigeru 2010) postulated that all the mammalian middle ear ossicles are derived from the second arch.

Furthermore, Reichert has mainly studied the embryogenesis of the second visceral arch, which was later named by him as the cartilage of Reichert (Maier and Ruf 2016). In essence, Reichert's cartilage is described as a continuous cartilaginous formation in the second pharyngeal arch, and this is where structures such as the styloid process of the temporal bone, the stylohyoid ligament, and the lesser horns of the hyoid bone are derived (Rodríguez-Vázquez et al. 2006). Specifically, as Rodrigued-Vazquez, et al. noted, the styloid process of the temporal bone is

created by the organic process of Reichert's cartilage.

Conclusion

Nevertheless, the theory posited by Ernst Gaupp and Karl Bogislaus Reichert was the first to present a comprehensive synthesis of embryological and paleontological information explaining the evolutionary process of the structures of the mammalian middle ear (see Maier and Ruf 2016). Based on the materials and methods used during their time, their scientific discovery is mostly accepted by the wider scientific community. The clarifications and additions Ernst Gaupp's has provided have significantly contributed to the Reichert-Gaupp theory.

Reinforcement Delivery

Reinforcement Schedule

Synonyms

Fixed-interval schedule; Fixed-ratio schedule; Reinforcement delivery; Variable-interval schedule; Variable-ratio schedule

Definition

The arrangement and rules of reinforcement delivery in operant conditioning, defined in terms of number of responses required (ratio schedule) or time elapsed (interval schedule), and in terms of consistency of reinforcement delivery (fixed/variable schedule).

Introduction

In operant conditioning, behavior followed by a reinforcer is strengthened and is more likely to occur again (Skinner 1938). Reinforcement can be continuous (consistently presented every time an organism exhibits a desired behavior) or intermittent (delivered irregularly, based on a predecided schedule). Reinforcement delivery schedules vary on the basis of whether the reinforcement is given on the basis of the number of responses required (ratio schedule) or the time elapsed (interval

schedule). Further distinctions are related to the consistency of reinforcement delivery, resulting in fixed schedules (where consistent reinforcement is given every time a behavior is observed) or variable schedules (where reinforcement is not dependent on raw data (number of exhibited behaviors or minutes elapsed) but on the average of number of observations or of time interval, resulting in an unpredictable mode of reinforcement delivery. Four schedules of reinforcement exist: fixed-ratio, variable-ratio, fixed-interval, and variable-interval.

Methodology for Measuring Responses Under Different Reinforcement Schedules

Skinner created a mechanical device known as a cumulative recorder, to investigate how the rate of responding changed on the basis of the reinforcement schedule applied. The device produced a cumulative record, i.e., a graph that measured the total number of responses since the beginning of the experiment (Skinner 1959). Each response by the animal (rat or pigeon, usually) moved a pen moving horizontally at a slow speed on a piece of paper one notch up, thus indicating vertically the number of cumulative responses recorded up to that point in time (measured in minutes and seconds horizontally). Ferster and Skinner (1957) experimented with fixed (regular) and variable (unpredictable) modes of presenting ratio and interval schedules of reinforcement and showed they can alter the speed of learning (response rate) and extinction (cease of a behavior).

Ratio Reinforcement Schedules

In ratio reinforcement schedules, responses are reinforced on the basis of the number of responses exhibited by the organism. In a *fixed ratio schedule*, the reinforcer is presented after a predecided number of responses are exhibited (e.g., after five responses). Fixed ratio schedules produces high rates of response followed by a short post-reinforcement pause (Ferster and Skinner 1957;

Powell et al. 2017). Higher resistance to extinction is noted the less frequent the reinforcement previously received, a phenomenon known as the partial reinforcement effect (Mowrer and Jones 1945). More recent studies corroborate these findings. Rats previously given continuous reinforcement extinguished the previously reinforced response of approaching a goal location in a water maze sooner than those previously given partial reinforcement (Prados et al. 2008). In a *variable ratio schedule*, reinforcement delivery is based on the average number of responses needed to receive a reward (e.g., a slot machine), and it is thus unpredictable for the organism. This type of schedule results in a high response rate, with little or no post-reinforcement pause (Powell et al. 2017) and is highly resistant to extinction following cease of reinforcement (Ormrod 2016). Resistance to extinction in variable ratio schedules is high because the unpredictability of the reinforcement makes recognition of the cease of reinforcement more challenging compared to a fixed ratio schedule (Reynolds 1975).

Interval Reinforcement Schedules

In interval schedules, the presentation of reinforcement depends on the time interval elapsed. Reinforcement is delivered after the organism exhibits the first desired response following a predecided time lapse. In a *fixed interval schedule*, reinforcement depends on the exhibition of the first desired response after a predetermined and predictable time interval (e.g., after 8 min). A reinforcement schedule of this type results in a “scaloped” (curved upwards) response pattern, evidencing a post-reinforcement pause followed by a gradual response rate increase as the time interval is come close to completion (Powell et al. 2017). Response rate in this type of schedule is medium (a lower rate is observed compared to a fixed ratio schedule), and it is also less resistant to extinction (Ormrod 2016). In a *variable interval schedule*, the time interval elapsed for the presentation of reinforcement is less predictable as it depends on an average interval over a time period rather than a fixed one. This unpredictability

Reinforcement Schedule, Fig. 1 Schedules of reinforcement and response rate (Huitt and Hummel 1997)

results in a moderate and steady rate of response with little or no post-reinforcement pause (Powell et al. 2017) and has greater resistance to extinction (Ormrod 2016).

The figure below summarizes response rates according to schedule of reinforcement applied (Huitt and Hummel 1997). The hatch marks on each line on the graph denote the presentation of a reinforcer (Fig. 1).

Comparison of Different Reinforcement Schedules

More consistent reinforcement delivery (in fixed reinforcement schedules) results in a post-reinforcement pause, whereas less predictable reinforcement (in variable schedules) produces a steadier rate of responses.

Similarities between ratio and interval reinforcement schedules include a post-reinforcement pause is observed after each delivery of the reinforcer in both *fixed-interval* and *fixed-ratio* schedules, as well as a high rate of responding just before the delivery of the next reinforcer. Furthermore, both *variable-ratio* and *variable-interval* schedules maintain steady rates of responding with no predictable pauses. Major differences between ratio and interval reinforcement schedules include higher response rates in ratio schedules of reinforcement compared to interval schedules (Skinner 1938; Ferster and Skinner 1957; Zuriff 1970; Reynolds 1975) and the phenomenon of “ratio strain.” Whereas in interval

schedules responding is maintained even a very low rates of reinforcement, in ratio schedules responses become “strained” or irregular and eventually they cease (Ferster and Skinner 1957).

Baum (1993) suggested that theoretical accounts of reinforcement schedules should consider behavior as being dependent upon post-reinforcement activity, other unprogrammed activity, ratio-typical operant behavior, and interval-typical operant behavior.

Conclusion

The four different schedules of reinforcement (fixed-ratio, variable-ratio, fixed-interval, and variable-interval) produce distinctive operant behaviors. More consistent reinforcement delivery (in fixed reinforcement schedules) results in a post-reinforcement pause, whereas less predictable reinforcement (in variable schedules) produces more consistent performance, and behavior shows more resistance to extinction. Ratio reinforcement schedules produce higher response rates compared to interval schedules, although in interval schedules behavior can more easily be maintained at low reinforcement rates compared to ratio schedules.

Definition

Children or adolescents who are disliked by many peers and liked by few peers.

Introduction

Sociometric status refers to how well-liked or disliked an individual is by their peers. Children who receive many positive nominations (e.g., nominations for being liked) and few negative nominations (e.g., nominations for being disliked) are classified as popular, whereas children who receive many negative nominations and few positive nominations are classified as rejected. A child's sociometric status can

influence their social interactions, psychosocial adjustment, and academic involvement. Rejection from peers has been associated with negative developmental outcomes, such as loneliness, victimization, internalizing and externalizing problems, and low academic performance (Ladd 2006; Veenstra et al. 2007; Zettergren 2003).

Characteristics of Rejected Children

In general, rejected children possess fewer peer-valued characteristics, such as physical attractiveness, style, athletic competence, and a sense of humor, when compared to their peers. They are also rated to be less socially competent than their other peers and tend to be left out of peer activities (Hymel et al. 1993). Rejected children can be classified into two categories: aggressive-rejected and withdrawn-rejected children. In addition to low social status, aggressive-rejected children exhibit aggressive tendencies and behaviors which may elicit dislike and exclusion from their peers. They are rated as uncooperative, less socially competent, and having difficulty getting along with adults. However, in terms of peer-valued characteristics, they were not rated as negatively as withdrawn-rejected children and were not always excluded from peer activities (Hymel et al. 1993). Children who experience peer rejection and exhibit aggressive behavior were more at risk of developing externalizing problems, such as disruption in classrooms, hyperactive and distractible behavior, and delinquency. This effect was stronger during early to middle childhood than late childhood (Ladd 2006).

Withdrawn-rejected children display a slightly different profile than aggressive-rejected children. In comparison to their aggressive-rejected peers, withdrawn-rejected children are nominated more negatively by their peers in regard to not possessing many peer-valued characteristics. However, their social and behavioral conduct does not fare as poorly as aggressive-rejected children. Despite being able to cooperate with their peers and get along well with adults, similar to their peers of average

status, they are still excluded from peer groups and activities (Hymel et al. 1993). Additionally, children who are withdrawn and rejected by their peers are more likely to also experience internalizing problems, such as anxious and depressive feelings. These children were more likely to experience these problems in middle to late childhood than early childhood (Ladd 2006).

Victimization

In addition to being disliked by their peers, rejected children are also at a greater risk of being mistreated by their peers. Their low acceptance and social status within the peer group increase their vulnerability to victimization, especially by bullying aggression (Veenstra et al. 2007). Bullying refers to a specific type of aggression in which the perpetrator has greater power than the victim. Considering this power imbalance, it is understandable that children with low status are more often targeted as a victim in bullying (Volk et al. 2014). From an adaptive perspective, bullying may be a strategy for children and adolescents to gain certain evolutionary advantages, such as social status (Volk et al. 2014). Children and adolescents who use aggression instrumentally may choose to target individuals who are easier to victimize. Rejected children are more likely to be targeted for victimization because of their low social status and emotional and social vulnerability (Veenstra et al. 2007). Further, research has found differences between the two categories of rejected children when it comes to victimization. For example, withdrawn-rejected children are more likely to be a target of bullying because they are socially vulnerable and less likely to retaliate (Veenstra et al. 2007). These characteristics can make it easier for a powerful bully to aggress toward the victim. By choosing a victim who is less likely to retaliate or does not have friends to protect them, bullies are able to use aggression to gain certain benefits, such as social status, while minimizing potential costs. On the other hand, aggressive-rejected children may be a target of bullying due to their tendency to provoke mistreatment from their peers due to their aggressive behaviors and hostile

attribution bias (Schwartz et al. 2001). In this instance, bullying may be a reactive action instigated by the victim. Overall, it is important to consider that rejected children are not only experiencing more victimization than their average or high status counterparts, but that this increase in victimization may also be associated with other negative outcomes or poor adjustment.

School Adjustment

Given the low social acceptance and likability that rejected children experience, there are also concerns of school adjustment and well-being. For instance, a study conducted by Buhs and Ladd (2001) found that rejected children were more likely to experience poor treatment from their peers, report loneliness, perform poorly academically, and participate less in school. In general, these students have a lowered desire to attend school and are more disliked by their teachers in comparison to their average status peers. Additionally, rejected children are typically perceived by their peers to be poor students and perceived by their teachers to have low self-confidence and be involved in more conflicts than children of average status (Wentzel and Asher 1995). Rejected children tend to have poorer academic performance and intelligence levels, in comparison to their popular peers, who tend to score above average (Zettergren 2003). Further, it seems that rejected girls have negative attitudes toward school in general, while the dropout rate for rejected boys was significantly higher than other boys, emphasizing the potential risk factor academically for rejected children (Zettergren 2003). Moreover, research by Wentzel and Asher (1995) also found academic differences between aggressive-rejected and submissive-rejected children, in that aggressive-rejected children tend to have more issues academically. Specifically, aggressive-rejected children reported being less interested in school, more impulsive learners, and less likely to be civil and compliant in class. Further, these students were perceived by teachers as being less independent and less likely to be nominated as liked by both teachers and students, while

these same characteristics were not found in the submissive-rejected subgroup (Wentzel and Asher 1995).

Psychosocial Adjustment

Aside from victimization and poor school adjustment, rejected children may also face psychosocial challenges. A study by Nesdale and Lambert (2007) found that peer-group rejection significantly increased anxiety in rejected children. Further, as children get older, peer rejection was found to increase the child's risk-taking behavior, while peer acceptance was found to decrease this behavior (Nesdale and Lambert 2007). Low levels of peer acceptance during adolescence were found to be associated with lower levels of self-regulation and were found to affect their decision-making. These adolescents were less able to tolerate distress and were more emotionally sensitive when dealing with negative loss in their life (King et al. 2018). Further, since we know that research has demonstrated that being a victim of bullying can be associated with higher levels of social isolation, anxiety, and depression (Veenstra et al. 2007), these rejected children who are also victimized may be more at risk for these outcomes.

Conclusion

In summary, children who face peer rejection are at greater risk of experiencing a myriad of other negative developmental outcomes. For decades, researchers and practitioners have worked on how to alleviate the difficulties and maladjustment associated with peer rejection. An emphasis has been put into providing these children with social skills training and opportunities to integrate with their peers, such as strategic seating plans and classroom activities (Bierman 2004). By providing children a safe classroom environment without the fear of mistreatment and rejection from peers, rejected children can participate more confidently in class and improve their scholastic adjustment and

academic competence (Buhs and Ladd 2001). Furthermore, research has found that rejected children who possessed more peer-valued characteristics were less likely to be targeted for victimization, suggesting that this may provide an avenue for intervention (Knack et al. 2012). For example, participating in sports and peer-valued activities may allow these children to better integrate with their peers, develop peer-valued characteristics, and experience less rejection. Overall, peer rejection has negative and persistent implications for children in many areas of their life, which highlights the importance of early intervention so that these children may experience more positive developmental outcomes.

The threshold at which hosts of avian brood parasites reject a foreign egg, which can be adjusted according to their perceived risk of parasitism.

Introduction

The interactions between avian brood parasites, such as cuckoos or cowbirds, and their hosts have emerged as model systems to study coevolutionary processes under natural conditions. Instead of building a nest and tending their offspring, brood parasites lay their eggs in the nests of other birds and abandon the care of their young to the host. Adult parasites tend to remove or damage host eggs when depositing their own and parasite chicks generally eliminate the rest of the host's brood after hatching. Consequently, hosts evolve defenses against brood parasites, which select counteradaptations in parasites, further counteradaptations in hosts, and so on. While evidence of reciprocal adaptations and counteradaptations in hosts and brood parasites are evident at all stages of the host's nesting cycle (Feeney et al. 2014), interactions at the “egg-stage” of the nesting cycle, such as egg rejection by hosts, egg mimicry by parasites, and further discrimination abilities in hosts, are the best studied.

Rejection Thresholds in Hosts

The failure to successfully reject a parasite's egg, either through not rejecting an egg or mistakenly rejecting an own egg, can cost a host its nesting attempt as well as the time and effort it takes to raise the parasite's chick (see ► [Egg Rejection](#)). Studies across numerous host–parasite systems have demonstrated that the decision to reject an egg can be based on the egg color, pattern, and size of the foreign egg (Spottiswoode and Stevens 2010; Stoddard and Stevens 2010, 2011) and that rejection decisions are specifically tuned to biologically relevant stimuli (i.e., according to differences between naturally

produced egg colors), rather than simply total differentness in color (Hanley et al. 2017). However, mistaken rejection of own eggs can occur when own and foreign eggs closely resemble one another (Feeney et al. 2015), so hosts use cognitive mechanisms and additional information to increase their likelihood of correctly rejecting the parasite's egg(s).

When faced with the perception of being parasitized, several cognitive mechanisms have been identified in hosts that help them increase the likelihood of correctly discriminating the foreign egg(s) in their nest. For example, they can simply reject the odd egg in the clutch ("discordancy hypothesis") or reject an egg (or eggs) based upon comparison to a learned or innate template of what one's eggs should look like ("true recognition"). Most studied species appear to use a template-based recognition system; however, some have been reported to conform to simple discordancy mechanisms or use a combination of both (reviewed in: Stevens et al. 2013). While these mechanisms are intended to help identify foreign eggs, parasites can also exploit them: African tawny-flanked prinias (*Prinia subflava*) reject cuckoo finch (*Anomalospiza imberbis*) eggs according to an internal template; however, cuckoo finches regularly parasitize prinia nests, and as the number of foreign eggs in the nest increases, prinias require greater differences between foreign eggs compared to their internal template to reject the eggs, resulting in lower rejection rates in these nests (Stevens et al. 2013).

Hosts also weigh their decision to reject a foreign egg according to their perceived risk of parasitism. For example, Eurasian reed warblers (*Acrocephalus scirpaceus*), a primary host of the common cuckoo (*Cuculus canorus*), that live in areas with cuckoos more readily reject foreign eggs compared to those that live in areas without cuckoos (Lindholm and Thomas 2000) and the rate of egg rejection within populations varies according to parasitism rates across years (Thorogood and Davies 2013). Within a breeding attempt, individual reed warblers combine both personal (i.e., the sight of a cuckoo near

their nest) and social (i.e., the sight of a cuckoo near a neighbors nest, resulting from it being attracted by the neighbor's alarm vocalizations) information about the presence of adult cuckoos near their nest (Thorogood and Davies 2016) to inform their egg rejection decisions.

Conclusion

Egg rejection is among the commonest and best-studied defenses that hosts use to minimize the cost associated with brood parasitism. Rejection decisions are primarily based upon hosts being able to discriminate a foreign egg (or eggs) in their nest; however, they also employ cognitive mechanisms and weigh these decisions according to their perceived risk of parasitism to help ensure they correctly identify the foreign egg (or eggs).

Definition

Relational aggression is a form of aggression characterized by attempts to harm or threaten others through purposeful manipulation and damage to interpersonal relationships.

Introduction

Relational aggression is a form of aggression characterized by attempts to harm or threaten others through purposeful manipulation and damage to interpersonal relationships (Crick et al. 1999). Relational aggression is distinct from physical aggression in that it often occurs without physical force or the threat of it. Relational aggression can be considered a type of psychological aggression – a form of aggression that targets perceptions, feelings, or behaviors but is more specific in that it always targets relationships (Linder et al. 2002). Relational aggression may take direct forms (e.g., negative facial expressions) or more indirect forms that do not directly confront the target (e.g., rumor spreading). It can also be proactive (e.g., planned, purposeful, goal-directed) or reactive (i.e., impulsive or response to a perceived threat) and may be directed toward kin, peers, or romantic partners. Examples of relational aggression include humiliating the victim in front of others, excluding the victim from social activities, and flirting with others to make a romantic partner jealous. Below we discuss some correlates of relational aggression and its developmental trajectory.

Correlates of Relational Aggression

Although several individual differences relate to relational aggression, we focus our discussion on some of the most common ones, including gender, self-esteem, narcissism, the Big Five personality traits, and personality disorders.

Regarding gender differences, although men often show and report more direct and physical aggression, women often show and report more indirect and relational aggression (Archer 2004). These gender differences in relational (and physical) aggression are often socially and culturally reinforced over developmental time (see Development section below).

Although self-esteem tends to relate negatively to physical aggression, the link between self-esteem and relational aggression appears to be positive among adolescents (Golmaryami and Barry 2010). In addition, self-esteem may moderate the link between narcissism and relational aggression; adolescents with lower self-esteem have especially positive narcissism–aggression associations (Golmaryami and Barry 2010).

In contrast, although narcissism tends to relate positively to physical aggression, its link to relational aggression is more nuanced. For example, although some studies of adolescents have shown a positive link for narcissism (Golmaryami and Barry 2010), others have shown null effects or evidence suggesting mediation via dominance goals (Ojanen et al. 2012). As mentioned above, the simple narcissism–relational aggression link is more positive among adolescents with lower self-esteem (Golmaryami and Barry 2010).

The Big Five personality traits – extraversion, agreeableness, conscientiousness, neuroticism, and openness – are related to a host of behaviors, and relational aggression is no exception. For example, in a large sample of Greek adolescents, relational aggression related positively to neuroticism but negatively to – in descending order of magnitude – agreeableness, conscientiousness, openness, and extraversion (Kokkinos et al. 2017).

Relational aggression's links with personality disorders – particularly those in Cluster B (e.g., antisocial, borderline, histrionic, narcissistic, and

sadistic personality disorders) – have also been studied in normal populations of young adults. For example, relational aggression positively correlates with Cluster B (more so than Clusters A and C) disorders and, regarding specific personality disorders, correlates strongly with sadistic and antisocial personality disorders and moderately with borderline, histrionic, narcissistic personality disorders (Schmeelk et al. 2008); however, the links for antisocial and borderline appear to be stronger among women than men (Werner and Crick 1999). In addition, relational aggression in children has been linked to future social–psychological maladjustment in a longitudinal study (Crick et al. 2006). Relational aggression was moderately negatively related to perspective taking in college students (Loudin et al. 2003). Moreover, peer-rejected college students were more likely to score high on relational aggression than their more accepted peers (Werner and Crick 1999).

Development

Although relational aggression is common across the lifespan, people in different developmental stages display different forms and degrees of relational aggression. Below we provide an overview of the developmental trajectory of relational aggression from childhood to late adulthood.

Childhood

As social cognition skills develop, children exhibit more relationally aggressive behavior (Andreou 2006; Archer and Coyne 2005). Research has found that 3- and 4-year-old children display relational aggression (Ostrov et al. 2004). In addition, because preschool-age children have relatively immature social and cognitive skills, researchers posited that overt and direct forms of relational aggression (e.g., friendship withdrawal threats) are more common in early childhood, whereas covert and sophisticated forms of relational aggression (e.g., gossiping, spreading rumors) become more common in middle childhood (Crick et al. 1999). But because even preschool-age children can show complex

relationally aggressive strategies, young children may in fact possess the ability to display sophisticated relational aggression as well (Ostrov et al. 2004). Aside from maturation in social-cognitive abilities, developing strong social networks is also associated with higher relational aggression in children. Existing literature shows that children in middle to late childhood engage in relational aggression more than those in early childhood as social groups become more developed and exclusive at older ages (Archer and Coyne 2005).

How do children develop relationally aggressive behavior? Past studies found family environment and parenting, such as parenting styles, marital conflicts, and parent-child conflicts, play an important role in children's development of relational aggression (Hart et al. 1998; Ostrov and Bishop 2008).

Regarding gender differences, as children learn about gender roles, girls (vs. boys) engage more in relational aggression because this form is often considered more gender-appropriate. But prior research has produced mixed results. Although some studies showed that girls (vs. boys) displayed more relationally aggressive behavior (e.g., Ostrov et al. 2004), others found trivial gender differences (e.g., Card et al. 2008). Researchers posited that gender differences in relational aggression may not exist at early childhood but increase in middle to late childhood (Archer 2004; Archer and Coyne 2005).

Adolescence and Young Adulthood

Relational aggression often reaches its peak during adolescence as adolescents enhance their social-cognitive abilities and understandings of others' perspectives. Consequently, aggressive adolescents use more relationally aggressive behaviors to achieve social success (Voulgaridou and Kokkinos 2015). Moreover, as status and peer relationships become important to adolescents' self-identities, some adolescents – especially girls with negative self-images – may have greater motivations to control and manipulate peer relationships (Moretti et al. 2001). In young adults, involvement in relational aggression remains common but occurs more frequently between

romantic partners than among peers (Goldstein 2011), possibly because many young adults view establishing romantic relationships as an important goal.

Researchers have argued that adolescent girls (vs. boys) display more relationally aggressive behavior and that this gender difference is the most salient during this stage (Archer 2004; Moretti et al. 2001). In young adults, however, no gender difference in relational aggression was found (Goldstein et al. 2008; Linder et al. 2002; Murray-Close et al. 2010), even though women tend to use relational aggression with romantic partners, whereas men do so more with peers (Murray-Close et al. 2010). One possible explanation for the null gender difference in young adults is that rates of relational aggression are more stable for women over time, whereas men increase relational aggression during young adulthood (Archer 2004; Archer and Coyne 2005).

Adulthood and Older Adulthood

Although research on relational aggression after young adulthood is scarce, relationally aggressive behavior is not uncommon in adults and older adults (Murray-Close et al. 2010; Trompetter et al. 2011; Walker et al. 2000). In fact, in adulthood, rates of direct aggression decrease while rates of indirect aggression increase (Archer and Coyne 2005; Walker et al. 2000). This may be because overt and physical aggression might have too high a cost, especially in work settings (Archer and Coyne 2005). Thus, indirect, relational aggression can occur more frequently in middle-aged adults and older adults (i.e., ages ≥ 55 years; Walker et al. 2000).

Similar to young adults, research suggested few gender differences in adults or older adults (Archer 2004). Nevertheless, perceived gender roles relate to relational aggression in older adults (Walker et al. 2000). That is, people who perceived themselves as being more stereotypically masculine (e.g., assertive) were more inclined to engage in indirect, relational aggression. Because older adults are less able or willing to engage in overt aggressive behavior, they often use more

subtle and sophisticated forms of aggression to harm others relationally.

Consequences, Implications, and Applications

Relationally aggressive people often have or experience higher social intelligence, peer rejection (Andreou 2006), bulimia, and antisocial and borderline personality disorders, as well as lower levels of prosocial behavior (Werner and Crick 1999). In contrast, victims of relational aggression are more likely to be obese or overweight (Janssen et al. 2004), have mothers with less education (Jansen et al. 2012), and have chronic disabilities (Ung et al. 2016). Regarding romantic relational aggression, both perpetrators and victims are often more insecurely attached, socially anxious, and ruminative and have more depression and anxiety symptoms (Goldstein et al. 2008).

Relational aggression often negatively affects its victims. Targets of relational aggression are more likely to experience loneliness and depression and have lower self-worth (Prinstein et al. 2001). Furthermore, relational victimization can predict future social phobia symptoms (Storch et al. 2005).

Of course, relational aggression can also harm its perpetrators. Peer-directed relational aggression predicts depression and anxiety symptoms, whereas romantic relational aggression only predicts these symptoms in girls (Ellis et al. 2009). In addition, relationally aggressive adolescents are more likely to experience peer rejection themselves, which could then make them targets of relational aggression by others (Wang et al. 2015). Relational aggression also negatively affects romantic relationships; both relational aggression and victimization relate to lower relationship quality (Linder et al. 2002).

Conclusion

Limitations and Future Directions

One limitation of relational aggression is that it can be difficult to measure. Because relational aggression is typically a socially undesirable behavior, self-reports may be biased because

people underreport it. To address this concern, some researchers supplement self-reports with peer, parent, or teacher reports (Golmaryami and Barry 2010; Ojanen et al. 2012), which, because of self-report biases, are more likely to be accurate. Another measurement issue concerns using the same instrument (e.g., survey, behavioral checklist) over developmental time, because what may be considered relational aggression to a 5-year-old may have little relevance to a 15- or 25-year-old. Thus, it is imperative that researchers continue to improve and refine the assessment properties of relational aggression measures. In addition, because much of relational aggression is inherently clandestine – arguably the “best” perpetrators intimidate victims enough not to report it – researchers may wish to broaden their assessment to include multiple peer reports. One way to do this would be to use social network analysis to survey entire classrooms or peer groups about relational aggression. Such designs can yield dyadic assessments of relational aggression between each pair of students in a classroom.

Treatment and Intervention

Given the substantial psychosocial impact of relational aggression, researchers have sought interventions to assuage its harmful effects. In school settings, social support from both peers and teachers has been shown to buffer against some of the negative effects of relational victimization, and as such, programs that help build teacher–student and peer–peer relationships and encourage people to solicit social support may help to improve victims’ qualities of lives (Flaspohler et al. 2009). Similarly, intensive school-based anti-bullying programs can decrease bullying by 20–23% and decrease victimization by 17–20% (Ttofi and Farrington 2011). Although this was found when examining bullying more broadly, similar school-based programs may also be effective in decreasing instances of relational aggression. Research into interventions for relational aggression in romantic relationships is less established; working to understand and modify the power dynamics and communication patterns in romantic relationships could likely decrease

instances of relational aggression in these relationships (Coyne et al. 2017).

Uncertainty of biological kinship

Definition

The term relationship uncertainty here does not refer to uncertainty about the status of a current romantic relationship but to a biological kinship uncertainty due to paternity uncertainty. For example, how certain is the biological relationship between two cousins where maximally two links of doubted paternity (father, father's brother) can be involved?

Introduction

Already Roman law stated that only motherhood is certain, and paternity uncertainty was also dealt with in the new law introduced with the Code

Napoléon (for example, “Scrutiny as to paternity is forbidden.” Title VII. Of paternity and filiation, Chap. III. Of natural children). Maternity certainty has remained certain, except for occasional mix-ups in maternity wards, until in-vitro fertilization became possible several decades ago. But for the long natural history of humans, paternity uncertainty threatened males to misdirect their costly paternal investment into the descendants of rivals. The asymmetry between maternity and paternity certainty is assumed to be one of the reasons why fathers tend to invest less in their offspring than mothers do. This assumption is supported by the finding that the perceived facial similarity between father and offspring, which is one of several possible kinship recognition mechanisms, is associated with paternal investment and emotional closeness to the offspring (Alvergne et al. 2010).

From Paternity Uncertainty to Relationship Uncertainties

The asymmetry between maternal and paternal certainty can be extended to relationship (kinship) uncertainty, with the hypothesis that feelings of closeness and the tendency to behave altruistically towards kind depends on the number of kinship links where paternity certainty may enter. For example, grandparental investment into grandoffspring may have up to two paternity uncertainty links: none for the maternal grandmother, one each for the maternal grandfather and the paternal grandmother, and two for the paternal grandfather. Euler and Weitzel (1996) could show that the number of paternity uncertainty links, that is, the relationship uncertainty, correlated negatively with the amount of grandparental solicitude as rated by adult grandchildren.

The study of grandparental investment is complicated by the fact that grandparents usually come in pairs, and the within-pair mutual influence may confound the investment for each single grandparent. This problem of co-residence as a confound can be circumvented by the study of the investment by aunts and uncles because the

brothers and sisters of the parents, unlike grandmothers and grandfathers, typically do not live together and thus invest into nieces and nephews independently of each other. It has been shown that the investment by consanguineal aunts and uncles (relatives by blood as opposed to aunts and uncles by marriage) is influenced by links of paternity uncertainty: The offspring of sisters reported to have received more care than those of brothers (Gaulin et al. 1997; Hoier et al. 2001).

The logic of differential investment into kin as a function of relationship uncertainty can be extended to cousins as well. A person has no uncertainty link with the offspring of his or her mother’s sister, one uncertainly link each with the offspring of father’s sister and mother’s brother, and two uncertainty links with the offspring of brother’s brother. Jeon and Buss (2007) could show that emotional closeness, empathic concern, and contact frequency with these types of cousins varied accordingly.

The Prevalence of Paternity Discrepancy

So far we have not quantified the paternity uncertainty which may occur at each paternal link. Obviously, the individual paternity uncertainty varies with individual circumstances, for example, the possibility of contact of the mother with other men during the time of conception. But how much paternity discrepancy (assuming paternity incorrectly; paternity confusion) has occurred in the ancestral past, and how much occurs these days in our societies? The amount of paternity discrepancy in the ancestral past has been estimated from the magnitude of the differences of investments into relatives of the next generation (nephews, nieces, and grandchildren) between the female and the male line. These estimates are just rough ones due to metrical problems of quantifying the differences. Gaulin et al. (1997) and Hoier et al. (2001) suggested from their estimates that in the evolutionary past the misattributed paternity must have occurred somewhat over 10 % of the cases. How does this number compare with recent paternity discrepancies?

In an earlier review Macintyre and Sooman (1991) reported that paternity discrepancy prevalences from prenatal genetic screening data varied between 1.4 % and 30 %, depending on country, ethnicity, and social milieus, with an average of about 10 %, a number which has been reported up to date in both scientific and popular writings. However, later studies cast doubt on the present-day truth of this number, at least for Western industrialized countries. In a meta-analysis, Voracek et al. (2008) showed that during the last century the reported paternity discrepancy prevalences slightly declined over the decades, arriving at a number of about maximally 3 %. The most recent reliable study known to the author (Wolf et al. 2012) reports a prevalence of 1 % for Germany, a number which is in accordance with data reported from the United Kingdom and Switzerland. The reason for this decline can only be surmised, with increased availability of effective birth control and less restricted choice of long-term heterosexual partners being likely candidates. But this low prevalence of paternity discrepancy has not changed the motivational structure of humans. They execute ancestral adaptations and treat their kin as if misattributed paternity still occurred relatively frequently.

Conclusion

Paternity discrepancy is nowadays considerably lower than assumedly has been in the past, but humans still execute ancestral adaptations. Therefore, relatives with fewer paternity uncertainty links, like offspring of sister, are emotionally closer than relatives with more paternity uncertainty links, like offspring of brothers.

Culture	The customs, beliefs, values, traditions, and knowledge shared by a society or community, which are transmitted from generation to generation
Race	A socially constructed concept that refers to a category or group of people that share a common ancestry, physical characteristics, and/or language

Introduction

Historically, the relationship between culture and race has been a source of debate. Although it was originally believed that race differed from culture in that race was a biological construct, findings from human genetics research have challenged the view that race is genetically determined. In particular, research showing that there is more within- than between-group variation in races led scholars to conceptualize race as a social, rather than biological, construct (Worrell 2015). The conceptualization of race as a social construct has increased uncertainty regarding the relationship between culture and race. That is, although scholars originally distinguished race from culture by viewing race as a biological construct,

establishing both race and culture as social constructs blurred the distinction between the two. Today, the distinction between race and culture is not completely clear, with some scholars arguing that culture and race are separate and different constructs (Phinney 1996), whereas others argue that the constructs are related and even refer to the same concept (Worrell 2015).

Race as a Social Rather than Biological Construct

For years it was believed that race was a biological construct that referred to a group of people who inherited certain physical characteristics (e.g., skin color; Worrell 2015). In science, race was used to describe the relationship between a person's ancestry and genes (Yudell et al. 2016). However, scientific research has consistently indicated that there is no gene or set of genes that are specific to one racial group. In addition, research has shown that there is great genetic heterogeneity within racial groups and more genetic variation within than between racial groups (Cosmides et al. 2003; Yudell et al. 2016; Worrell 2015). Research in social psychology has provided further support for the idea that race is a social construct through findings indicating that the conceptualization of race is different across cultures (Chen et al. 2017). Although scholars generally agree that race is a social construct, there continues to be a widespread use of race as a biological variable in scientific research, and some scientists have called for an end to the use of race as a biological variable given that it does not have a genetic basis (Yudell et al. 2016).

Evolutionary Explanations for Race

Despite the lack of biological support for distinct racial categories, the concept of race continues to be commonly accepted. Although research originally suggested that race was automatically encoded, it was determined that race was likely not built into our evolved cognitive machinery, since hunter-gatherers traveled primarily by foot,

making it highly unlikely that they would encounter individuals from different races (Cosmides et al. 2003). Other research findings also spoke against the automatic encoding of race by indicating that categorization by race may be dramatically reduced when presenting individuals with contexts in which race is irrelevant for determining coalitions (Kurzban et al. 2002). As a result, different evolutionary hypotheses have been proposed to explain the nature of race encoding (Cosmides et al. 2003). One particular theory proposed by Kurzban and colleagues (2002) suggests that race encoding results from an alliance detection system that evolved to identify coalitions and alliances. According to the theory, human cognition is not designed to automatically detect race. Instead, race signals coalitional alliances, thereby allowing individuals to successfully navigate the social world.

associated with race because both concepts refer to groups with a common ancestry. However, ethnicity may be distinguished from race in that it refers to groups of individuals with a common geographic origin or nationality, whereas race does not. Additionally, unlike ethnicity, race has been used to refer to groups of individuals with similar phenotypes. Nevertheless, there is confusion regarding the two concepts; for example, the term Latino/a refers to an ethnicity but is often perceived as a race because individuals from this ethnic group may share physical characteristics. The lack of clear-cut distinctions between race and ethnicity has resulted in discussions regarding the difference between the two concepts, with some scholars proposing that race and ethnicity should be conceptualized as a sole construct, such as “racial/ethnic identity” (Grosfoguel 2004).

Relationship Between Culture and Race

Culture and race are closely related in that they share several key characteristics (see Worrell 2015). First, both culture and race refer to an individual's membership in a particular social group. Additionally, both terms refer to groups of individuals with a common ancestry or history, as well as similar values and beliefs. In this way, culture and race are closely related constructs used to categorize social groups based on certain key characteristics. However, one clear distinction between culture and race is that, traditionally, culture has been applied more broadly to include groups of people who share a common nationality, art, and/or religion, whereas race does not usually include these characteristics.

Another way in which culture and race are related is through the concept of ethnicity. Ethnicity is a term used to refer to a group of individuals who identify with or belong to a particular cultural group (American Psychological Association 2018). Thus, according to this definition, culture is fundamental to the concept of ethnicity. Importantly, both ethnicity and culture may refer to groups of individuals with a common nationality. Ethnicity has also been closely

Conclusion

The conceptualization of race as a social, rather than biological, construct was important for eliminating misconceptions regarding innate differences between racial groups, but the new conceptualization also resulted in uncertainty regarding the relationship between culture and race. That is, the original view that culture and race were separate constructs became less clear once it was determined that there was no biological basis to race. The lack of clear-cut genetic differences between racial groups has led some to argue that culture and race refer to the same concept (Worrell 2015). However, others contend that the two terms should be considered separate concepts (Phinney 1996). From an evolutionary perspective, both race and culture serve similar social functions in that both may signal kinship or alliance. Overall, it can be said that culture has traditionally been used as a broader categorical concept based on factors such as ancestry, language, religion, or nationality, whereas race has a more limited categorical scope because it was mainly used to refer to groups of individuals with a common ancestry and/or common physical characteristics.

However, recent research highlighting the influence of culture on perceiving an individual as a member of a particular race (Chen et al. 2017) has further contributed to the uncertainty regarding the exact nature of the relationship between culture and race.

In general, the consensus is that both culture and race are related because they are social constructs used to categorize groups of individuals with a common ancestry (Worrell 2015). Additionally, research suggests that racial categorization is somewhat subjective (Chen et al. 2017). In general, relative to race, culture has been traditionally applied as a broader social categorization concept. Thus, the conceptual and functional similarities between culture and race (e.g., group of individuals who share a common ancestry) have led to debates regarding the relationship between the two. Continued research on culture, race, and ethnicity will likely contribute more information regarding the exact nature of the relationship between culture and race.

Definition

Gender refers to the collection of psychological traits that differ between the male and female sexes. Often, the terms gender and sex are used interchangeably; however, sex may be used when discussing the biological or genetic differences between males and females, while gender may be used to refer to psychological traits. Sexuality is very broad and refers to feelings, behaviors, and identities associated with sex. Here, we discuss

the literature which has reviewed the relationship between sexuality and gender.

Introduction

Men and women differ in many aspects of sexuality. From an evolutionary psychology perspective, men and women faced different reproductive problems in evolutionary history and, thus, adapted different reproductive strategies. While men and women may have many adaptive similarities to solve many problems, mating and reproduction are two areas where several problem-solving strategies are dichotomized. Men's sexuality is often characterized as more open to sexual behaviors, thoughts, and experiences, while women's sexuality is characterized as less open to these arenas.

Causes of Gender Differences

Gender influences sexuality via the effects of sexual differentiation. This can include the impact of sexual and natural selection on sex differences, leading to differences in sexual behavior (see ► [Sex Differences in Long-Term Mating Preferences](#); ► [Sex Differences in Short-Term Mating Preferences](#)). For example, parental investment theory suggests women would be more selective regarding sexual encounters and partners because they risk committing to a pregnancy and subsequent child-rearing (see ► [Parental Investment Theory](#)). Biological variations, including hormonal influence, also appear to influence sexuality. For example, testosterone influences sex drive in both men and women, and a higher testosterone level in any individual is associated with higher sex drive. In men who are experiencing low testosterone, a common complaint is a lack of sex drive. While estrogens play an important role in women's sexuality (e.g., influencing vaginal lubrication and elasticity), clinical studies suggest that women's sex drive is improved by taking exogenous testosterone and estradiol, but not improved by taking solely estradiol (see ► [Ovulatory Hormones](#)). Regarding sex drive, Lippa

(2009) found that gender differences in this variable were very large and very stable across different cultures suggesting a strong biological determinant.

Some aspects of sexuality show gender difference patterns that suggest interacting biological and cultural influences. For example, gender differences in sociosexuality described by Lippa (2009) were moderated by several cultural variables including the relative level of gender equality and economic development within each culture tested. This is consistent with observations that women's sexuality appears to be more plastic and sensitive to cultural or social influence than men's sexuality (see ► [Female Homosexuality and Bisexuality](#)).

Gender and Sexual Behavior

In this section, we highlight some of the findings that find gender differences in sexuality. This section is not intended to be an exhaustive list of all findings that show gender differences in sexuality.

Men tend to masturbate more often than women and pay for sex more often than women, while women tend to get paid for sex more often than men, and men are more likely to report engaging in sexual fetishism (Baumeister 2000; Lippa 2009). Well-replicated, large effect gender differences in sex drive are often utilized to explain these behavioral differences (Peplau 2003; Lippa 2009). There are relatively fewer studies to draw from regarding the effects of sexual orientation, but it appears that homosexual men and homosexual women tend to exhibit male-typical and female-typical sexuality, respectively, in the domains described above (Peplau 2003) though of course with the exception of their preferred partner's gender.

Men tend to seek out sexual variety more so than women (see Baumeister 2000 for an overview). For example, women are less likely to seek out and engage in extra-pair sexual intercourse compared to men; and women are less likely to have multiple sexual partners at any one given time compared to men. Women are less likely to pay for sexual intercourse compared to men. Men

are more likely to seek out, or accept an invitation for, casual sex relationships compared to women, while women report more regret or negative associations with casual sex compared to men. In the USA, casual sex or “hook-ups,” particularly among college-age students, are more sought after by men than women, while women report feeling more regret and shame about casual hook-ups compared to men (Garcia et al. 2012).

Women’s sexuality appears to be more fluid than men’s sexuality (see ► [Female Homosexuality and Bisexuality](#)). Women report changing sexual orientations more so than men, and women report less stringent sexual proclivities for one sex over another compared to men.

Gender and Sociosexuality

Sociosexuality refers to attitudes, thoughts, and behaviors regarding non-committal sex (see ► [Sociosexuality](#)). Numerous studies find men and women to differ on all three domains of sociosexuality. Men tend to be far more permissive regarding attitudes toward casual sex and more likely to engage in casual sex compared to women (Schmitt 2005; Sprecher et al. 2013). This appears to be stable across cultural groups, though there is plenty of cross-cultural and interindividual variation.

There are additional findings which suggest that gender differences in sexuality are smaller than previously discussed (Baumeister and Twenge 2002) or at least decreasing over recent decades (Peterson and Hyde 2011), implicating an influence of social learning and/or societal structure influences on gender based behaviors, including sexuality. These theories suggest that if social or cultural “scripts” or norms are influencing the perceived gender differences in sexuality, then removal of these scripts or norms would result in more similarity between sexuality and genders. In one study, Jankowiak and Escasa-Dorne (2016) reviewed profiles of individuals on a popular casual sex dating website to see if gender differences emerged. Jankowiak and Escasa-Dorne

suggest that if sexual proclivities of men and women were influenced by social or cultural norms, then an outlier group of individuals who are open to casual sex should have diminishing differences in their online sexual personas. However, their findings suggest that men and women’s profile pages reflected the well-documented gender and sexuality findings such that men were more open to casual sex and variety than women. Yet, the use of women on casual sex websites is also a reminder that sexual behaviors or proclivities are still variable within genders and that cultural influence can influence the degree of difference seen between genders (see also Lippa 2009; Peterson and Hyde 2011).

Gender Variance and Diversity

While most studies dichotomize gender into men and women, many groups have third or multiple genders, androgenders, or transgender individuals whose gender categories may not be included in the research discussed in this entry. While little research has explored the relationship between gender diversity and sexuality directly, the Fa’afafine of Samoa (see entry Fa’afafine), Hijrahs of India, and the mātānū of Tahiti tend to prefer men as sexual partners. Sadhins of India typically remain celibate, likely due to culturally imposed expectations (Nanda 2000). In Brazil, three gender variations (travesty, viado, and bicha) are defined by whether an individual is penetrated, or penetrating, during sexual intercourse.

Conclusion

Evolutionary theory hypothesizes that men and women faced different reproductive strategies, selecting for variation in sexuality between men and women. Data on sexuality, including sociosexuality, psychological traits, and sexual behaviors, suggests that men and women differ in numerous areas of sexuality.

Definition

Sociosexuality was originally designed to capture individual differences in people's willingness to engage in sexual behavior outside a formally/informally committed relationship. Work on the construct has moved from simple one-dimensional models, to models that incorporate the behavioral, attitudinal, and behavioral intention aspects of motivations to engage in casual sex, to, finally, encompassing an expansive model that describes a two-dimensional coordinate system composed of short-term mating interest and long-term mating interest. This model is especially useful in examining the emergent nature of the variety of apparent relationships that characterize the sexual landscape today.

Introduction

Since Kinsey (circa 1953), it has been clear that there is a wide variety of sexual behaviors men

and women engage in. Despite this, there is a pervasive myth of heterosexual monogamy in laypeople and researchers. This myth implies that the only acceptable form of sexual behavior is when it occurs in a committed relationship. While there are various reasons individuals might disapprove of sex outside of this context (e.g., health, religious), it is clear that individuals do engage in such behaviors in various relationship contexts. A more complete and accurate picture of human sexuality demands researchers to consider the various forms of sexuality individuals engage in. Indeed, even a cursory look at the animal kingdom reveals an apparently infinite array of sexual variety.

In the early 1990s, there was a paradigm shift in scientific thinking about the variety of sexual behavior and attitudes. Up until then, sex out of the context of marriage (i.e., casual sex) was seen as a pathology warranting treatment. Evolutionary psychologists began pointing out that engaging in casual sex might be adaptive for men and women (Buss and Schmitt 1993). By no longer pathologizing casual sex, researchers opened the proverbial floodgates to scientific inquiry into various questions related to motivations and measurement of people's willingness to engage in casual sex (see Jonason and Balzarini 2016).

Relationship Choice

In efforts to try and account for individual differences in relationship choices, Simpson and Gangestad (1991) developed a construct called "sociosexuality." This construct is meant to describe individual differences in people's attitudes, behaviors, and desires for casual sex as a way to explain within – and between – sex relationship choices. For instance, items ask about willingness to have sex with someone sans feelings and how often individuals fantasize about someone other than their current partner. It has been quite useful in understanding broad-spectrum motivations to engage in casual sex, sex differences in such motivations, and is useful

in providing some insight into people's sexual psychology around the world.

However, there are a number of potential limitations with their conceptualization of sociosexuality. The one most attended to at present is its psychometric structure. For example, using the original scale's items, more advanced tests (i.e., confirmatory factor analysis) revealed that the scale was better described as a two-dimensional system of sociosexual attitudes and sociosexual behaviors, dimensions that differ in their associations with narcissism and hostility (Webster and Bryan 2007). This two-dimensional model was further improved in Penke and Asendorpf (2008) to include sociosexual desires. These researchers attempted to understand sociosexuality as a manifestation of the classic social psychological distinctions of attitudes, behaviors, and behavioral intentions.

Another limitation of the initial work on sociosexuality was that it treated human sexuality in a rather black and white, dichotomous manner with one-night stands and serious romantic relationships treated as the only relationships available to engage in. Partly, this may be the result of efforts to reduce cognitive effort and to simplify research. However, this is a suboptimal solution as between 25% and 75% (see Jonason et al. 2012) of sexual acts committed by adolescents and college students happen in the context of sexual relationships that lack formal commitment (in contrast to serious romantic relationships) but are recurring acts committed by those with more than a passing acquaintanceship (in contrast with one-night stands). In addition, individuals appear to engage in non-relational sex for reasons thought to be confined to serious romantic relationships (e.g., emotional intimacy; Jonason 2013). While prior research has treated all casual sex as the same, there is evidence that each has its own functions and characteristic types of sexual and emotional acts (Jonason et al. 2010; Jonason and Balzarini 2016).

If one takes a step back, however, the real problem with using the sociosexuality construct to account for variance in relationship choice is that it treats motivations to engage in casual sex

and motivations to engage in committed relationships as opposite ends of the same spectrum when there are likely multiple competing interests at once (see Jonason and Balzarini 2016). In a third conceptualization of sociosexuality (Jackson and Kirkpatrick 2007), researchers highlighted the theoretically important dimensions of long-term mating interest, short-term mating interest, and past sexual experiences. Such an attempt better highlights the multidimensional nature of human mating strategies and may better allow researchers to capture the range of potential relationships people may engage in. Despite this theoretically relevant dimensional structure, researchers have not taken a fully evolutionary approach to relationship choice.

Importantly, evolutionary theory, as applied to all manner of human existence including, but not limited to, relationship choice, suggests observable patterns in the world emerge from the competitive interactions of lower-order agents/factors without any overarching plan/planner, that is, relationships, as seen from our day-to-day lives, are not natural kinds but, instead, are the result of processes going on within people, societies, and couples. Relationships are likely the result of negotiations or, in other words, responses to numerous socioecological constraints imposed by those within (e.g., the partners) and outside relationships (e.g., society), but also ecological conditions like the availability of quality mates and resources (Jonason and Balzarini 2016). To treat relationships as distinct phenomena fails to deal with the fact that every relationship is different over a person's lifetime but also across individual relationships.

Emergent Relationships

In hopes of convincing the reader that relationships are emergent solutions to conditions, a review of some (but not all) relationship types is presented next (see Jonason and Balzarini 2016). For instance, polyandry tends to occur in locations where the means by which resources are extracted from the earth are so labor-intensive that it takes

multiple men to work their farm. Alternatively, polygyny is an option made available by a localization of resources. And last, polyamory might be a function of an interaction of individual differences in jealousy responsivity, the cobbling together of one's sexual and security needs from multiple sources, and the desire to seek secondary benefits like excitement. While these options represent "extreme" solutions to the psychosocial and reproductive tasks organisms, including humans, face, they are expressions of a mating system that is flexible to "cultural" conditions. Less extreme solutions might be found in booty-call relationships or friends-with-benefits where latent mating systems interact with technologies (e.g., mobile phones) to enable mating success (Jonason et al. 2009, 2010).

An important aspect of this emergent solution hypothesis (see Jonason and Balzarini 2016; Jonason et al. 2012) is that there are winners and losers in the battle of the sexes as would be expected from sexual strategies theory or a parental investment theory (Buss and Schmitt 1993). In terms of the present discussion, in serious romantic relationships, women may gain more than men do as the former have secured the dedicated resources of a single man. In contrast, in one-night stands, men may gain more than women in that they gain access to low-investment sex. However, most research assumes stark zero-sum solutions in relationships. Instead, in negotiations, middle-ground or hybrid relationships may emerge in the form of mildly positive-sum relationships where both partners win something when they compromise a little. If we assume that people have ideal standards in their partners, any willingness to deviate from those ideals acts as a compromise (Li et al. 2002). While a woman engaging in a one-night stand may have to fully compromise what she wants (excepting sexual pleasure), a woman who engages in a booty-call relationship may get some of what she wants. In an idealized world, people would not need to compromise, but as the alternative to not doing so is potential reproductive oblivion, evolution would have fashioned flexibility into the system.

Conclusion

In conclusion, the utility of sociosexuality in hopes of accounting for individual differences in relationship choices has progressed like most good science, starting with simplicity and advancing to a more complicated, comprehensive conceptualization known as strategic pluralism (Gangestad and Simpson 2000). This hypothesis suggests that flexibility in mating systems is in-built as over generations individuals who could be flexible in their relationship choices had increased reproductive fitness. For instance, the purely short-term maters would have had trouble securing a partner, and their offspring would have not fared well, whereas the purely long-term maters would be overly invested in a single partner and unable to switch if the need emerged. Indeed, even gibbons (sp. *Hylobates*), the most “monogamish” (lesser) ape, are not fixed into monogamy. Instead, humans, like gibbons, may be able to swing from one mating strategy to another as the need arises. That is, the sexual variety observed in the world is the solution, not the problem to life’s greatest task: reproduction.

Definition

The process of ending a relationship by the voluntary action of at least one partner.

Introduction

Most ancestral mammalian species didn't form long-term male-female pair bonds. Males mated with estrous females, and when the female went out of estrus, the relationship ended. Dissolution only became an issue when the human species came into existence, at which time males and females began living together in long-term relationships. During the hunting and gathering era, the dissolution of these relationships was apparently simple and without serious consequences, either for the couple or their offspring. However, following the development of agriculture, dissolution became more problematic. Children needed paternal investment from a biological father, accumulated wealth made inheritance possible and paternity important, and rising religions condemned adultery and divorce.

Currently, in many societies, relationship dissolution is once again becoming easier, due to changes in mores and technological developments such as birth control, with consequences that are still becoming apparent (see, e.g., Draper and Harpending 1982).

Human Evolution and Relationship Dissolution

For the most part, mammals don't engage in long-term male-female relationships. Beach (1976) estimates that "perhaps 90% of all mammals are seasonal breeders" (quoted in Symons 1979, p. 79). Even in mammalian species that live in social groups (herds, packs, and troops), long-term male-female dyads are rare.

Some of our distant primate relatives, marmosets and tamarins, do engage in male-female pair bonding (e.g., Dunbar 1995). Gibbons live in "small groups which superficially resemble the

human family because they are composed of a mated pair and their immature offspring", but, according to Lancaster, the "gibbon 'family' is a common pattern for . . . mammals in the tropics and does not represent a predecessor to the human family" (Lancaster 1975, p. 34). The Hamadryas baboon "harem" is another primate social arrangement that seems to be a precursor of a version of the human family (Kummer 1968), but it is "not so much a unit adapted for mating as it is for foraging in an environment of scarce and scattered food resources" (Lancaster 1975, p. 33).

Among our closest primate relatives, the chimpanzees, males are usually interested in bonding with females only when females are in estrus (e.g., Van Lawick-Goodall 1971; De Waal 1989), although recent observations indicate that "male chimpanzees living in an exceptionally large community display long-term tendencies to associate with particular females" (Langergraber et al. 2013).

With some exceptions, the basic reproductive strategy of mammalian males is to impregnate as many females as possible, while the female strategy is to nurture a relatively small number of offspring. The male strategy is perpetuated by basic psycho-physiological mechanisms common to all mammals (Gray 1971). These include the following:

Pursuit of Novelty

Every mammal responds to novelty with excitement and interest, an aspect of mammalian psychology that is well substantiated. In laboratory studies, a male "typically copulates with an estrous female several times and then stops. When the original female is replaced with a new estrous female, the male begins to copulate with the novel female" (Morton and Gorzalka 2015, p. 493). See also Schmitt et al. 2001.

Habituation and Sensitization

Every mammal is subject to habituation – a decrease of interest in, or attention to, a stimulus once it becomes familiar. It's what causes a stimulus that was once salient to fade into the background. Habituation enables animals to ignore

repeated stimuli once they prove not to be dangerous. Sensitization is the opposite of habituation. Animals become increasingly sensitive to repeated stimuli instead of tuning them out (Plaud and Gaither 1997).

Hunter-Gatherer Innovations: Marriage, Father, and Family

At some point, perhaps even before *Homo sapiens* came into existence, males and females began living together in dyads, with males hunting and females gathering. They shared the work of subsistence and raised their offspring more or less together, thus giving rise to the family. A group of related families formed the foraging band. Meat was shared with the entire band, while vegetables, fruits, and nuts were usually shared among the immediate family (Lee 1979; Lee and Devore 1976; Tonkinson 1978; Turnbull 1961.)

The institution of marriage arose, and males became *fathers* who provided significant paternal investment to the children of the band. Striving for dominance among males was muted because virtually every male could have a wife. The family and the band replaced the dominance hierarchy.

With the advent of long-term male-female pair bonds, reproductive strategies took a new turn. Females lost the obvious estrus of ancestral species and became receptive to sex during times when they weren't ovulating. Males developed a new set of emotions, reinforced by the members of the extended family, which urged them to stay with a female partner (or partners) and invest in the care of offspring, while females sought a relationship – a marriage – with a male who could be expected to invest, often an older man, preferably a successful hunter.

However, if contemporary hunter-gatherer practices are any indication of what went on in ancestral bands, divorce and extramarital sex were common. The new male desire to stay with a partner coexisted with the ancient drive to impregnate many females. As Symons notes:

a male hunter/gatherer with one wife (who will probably produce four or five children during her lifetime) may increase his reproductive success an

enormous 20 to 25 percent if he sires a single child by another woman during his lifetime. If he can obtain (and support) a second wife, he may double his reproductive success. The reproductive realities facing his wife are very different. She will bear four or five children during her lifetime whether she copulates with one, ten, or a thousand. (Symons 1979, p. 161)

Married males didn't stop trying to have sex with other women. In all hunter-gatherer bands that have been studied, illicit trysts were common. For example, anthropologist Asen Balikci writes that some Netsilik Inuit men "...were well known for their sexual enterprise..." (Balikci 1970, p. 160). Although their behavior sometimes caused quarrels and was disapproved of, it was tolerated.

A small percentage of contemporary hunters had more than one wife in addition to the extramarital sex (Turnbull 1961; Tonkinson 1978; Lee 1979; Balikci 1970), and it is likely that polygamy existed in ancestral bands.

Although the female strategy remained focused on nurturing offspring, now with a male partner in a band, women participated willingly in extramarital relationships. Shostak describes such affairs from the perspective of Kung women:

To succeed at and to benefit from extramarital affairs, one must accept that one's feeling for one's husband—"the important one," "the one from inside the hut"—and for one's lover—"the little one," "the one from the bush"—are necessarily different. One is rich, warm and secure. The other is passionate and exciting, although often fleeting and undependable. (Shostak 1981, p. 267)

Relationship Dissolution in Foraging Societies

First marriages are usually between a young woman who has recently entered puberty and an older man. Sometimes these first marriages last, but often they break up rather quickly. According to Shostak, most! Kung

experience one long-term marriage, although most are also married more than once. Dissolution of marriages by divorce is quite common. It usually occurs during the first few years of a marriage, before the couple has had children, and is usually initiated by the woman... No formalities or legal procedures are necessary, but emotions often run high. Arguments for and against termination may

go on for days or even weeks, as everyone in the village expresses a point of view. Eventually, a decision is made, and if the choice is separation, it ends there... The divorced girl or woman simply re-enters the category of highly desirable potential wives, to be sought after by eligible men. (Shostak 1981, pp. 130–131)

Among the Netsilik Inuit, the custom of wife exchange could precipitate the dissolution of the original marriage. Wife exchange often

...led to permanent separations. After temporary arrangements had been organized, the exchanges increased, and the men lost interest in their wives and decided to settle down permanently with their partner's wife. A new marital situation was thereby created, with the children following their mothers to their new houses. (Balikci 1970, p. 143)

Women in most hunter-gatherer societies could initiate breakups and have affairs without dire consequences, for themselves or for their children, because (1) they were equal partners with men in the work of survival and (2) the band as a whole was responsible for raising the children, not just the parents. For example, among the Mbuti:

...as far as the child is concerned, all adults are his parents or grandparents... He knows his real mother and father, of course, and has a special affection for them and they for him, but from an early age he learns that he is the child of them all, for they are all children of the forest. (Turnbull 1961, p. 128)

Extramarital sexual relationships and relationship dissolution no doubt produced jealousy, anger, resentment, and sometimes violence in the bands of our ancestors, as they do today. However, it's important to note that a male's drive to have sex with many females did not necessarily dissolve his marital relationship. Nor did it have to cost him reproductive success – or damage his children – because paternal investment was provided by all the males in the band. Nor were women who engaged in extramarital affairs ostracized or condemned. The survival of children was not dependent on long-term conjugal relationships.

In general, when marriages ended, both males and females could find new partners, and the new arrangements were eventually accepted, or at least tolerated, by the other members of the band.

Although “sexually enterprising” males and females often caused tension and trouble, they weren't destructive of the social system.

Relationship Dissolution After the Agricultural Revolution

Once our species abandoned nomadism and settled down to farm, often with a husband and wife sharing all the labor and raising the children by themselves, things changed dramatically. Without the band to raise the children, the parental investment of the biological father became critical to their survival. Children without fathers tended not to do as well as children who did have fathers. In agricultural societies, if a male abandoned the mother of his children, they might not survive, and his own fitness would be compromised.

With agriculture came the ability to accumulate wealth – property and, eventually, money. These could be passed on to one's children. For people with something to pass on, paternity was a crucial issue. Wealth, inheritance, and the need for parental investment from a father turned the dissolution of a conjugal relationship into a far more serious issue than it had been in foraging bands. Breaking up could result in the loss of the support children were dependent on. This in turn could be a serious blow to a man's fitness. It could also mean financial loss for men, such as return of a dowry or payments to the wife's family. Staying with one's wife (and perhaps having affairs on the side) was often a better economic decision for males than divorce.

In addition, rising religions enshrined monogamy and faithfulness in many societies. “Thou shalt not commit adultery” became a centerpiece of morality in Judaism, Christianity, and Islam. For hundreds of years in Europe, divorce was a sin, and for hundreds of years, more women couldn't initiate it. Men's extramarital affairs were frowned upon, but women's affairs were punishable by death (and still are in some societies). Religious prohibitions put enormous pressure on both males and females to stay with the family despite their personal feelings and desires.

The Coolidge Effect

In societies where adultery was a sin and fidelity was expected, the mechanisms that served to break up relationships could cause serious trouble for couples and the society. Primary among them was the male drive to have sex with multiple partners, often referred to as the Coolidge Effect (Symons 1979; Wilson 1982; Morton and Gorzalka 2015).

The Coolidge Effect is the progressive decline in a male's interest in mating again and again with the same female combined with a heightened interest in new females. It is, essentially, the old mammalian male reproductive strategy that hasn't gone away. The persistence of the Effect in human males has been documented in a great many studies (e.g., Kinsey et al. 1961; Masters and Johnson 1966; Bermant 1976; Symons 1979; Dewsbury 1981; Wilson 1982; Schmitt et al. 2001; Morton and Gorzalka 2015). Thus, it is not surprising that in her cross-cultural study of conjugal relationship dissolution in many societies around the world, Betzig found that adultery was the most common cause of relationship dissolution. She also found that the "double standard" was also a common cross-cultural phenomenon:

In 25 societies, divorce follows from adultery by either partner; in 54 it follows only from adultery on the wife's part and in 2 only from adultery on the husband's. If marriage qualifies as near universal, so must the double standard. Almost every one of the causes of conjugal dissolution that might be related to infidelity is ascribed significantly more often to one sex than to the other. (Betzig 1989, p. 658)

The Coolidge Effect in Therapeutic Practice

Therapists who deal with sexual issues sometimes encounter men who may love their wives/partners but are forced either to give up sex or to look elsewhere for it, a situation which can begin to undermine the relationship. Men are often reluctant to admit that they aren't sexually interested in the woman that they love any longer. It's too frightening an admission for them to make and too painful to communicate to their partners. So they don't say anything and begin avoiding sex.

Then, often, a wall of silence arises between the man and his mate.

At first, many men in this situation begin to worry about their own potency. When they find that they are attracted to other women, they often experience a sense of relief that they're not impotent. At that point, a Coolidge-affected man may become sensitized to some aspect of his partner's behavior that didn't bother him before. Something negative about his partner sticks in his mind and can't be driven out: "She's such a nitpicker," "She's nagging me all the time." He may manufacture reasons to engage in an extramarital relationship or initiate a breakup.

Another way the Coolidge Effect leads to relationship dissolution is via the female response to it. Faced with a male's loss of sexual desire, women are likely to feel neglected and unloved. They begin to look around and are more likely to have affairs or to initiate a breakup themselves. Wilson notes that when women:

...are questioned about why they have extramarital sex, it usually turns out that their relationships with their husbands were in some way unsatisfactory at the time or that they saw other men as being in some sense superior to their husbands. . . . Another fairly common reason . . . is that they hoped to create some effect on their husbands, for example, getting revenge on them for similar behavior. (Wilson 1982, p. 51)

See also Greiling and Buss (1999).

The mechanisms noted above – the pursuit of novelty, habituation, and sensitization – can become very troublesome when long-term relationships are the goal. For example, humans in long-term relationships can become sensitized to nonsexual stimuli that were initially tolerated or tuned out. Humans can also habituate to sexual stimulation over time (Plaud and Gaither 1997). In the novelty phase, a partner's every move can be intensely rewarding, but as time goes by, the excitement and the charm fade.

For much of civilized history, economic necessity, social pressure, and fear of damnation kept many couples together who didn't want to be. Staying together may have maintained parental investment in children and kept the couple socially acceptable, but both the male and female

often led what Thoreau called “lives of quiet desperation.”

Relationship Dissolution Today

In many contemporary societies, relationship dissolution is once again becoming relatively easy, but new social and technological complications have been added. Among these new features are birth control, no-fault divorce, prenuptial agreements, financial independence of women, legal and governmental support for single mothers, decline in the power of religious prohibitions, social acceptance of long-term cohabitation without marriage, and custody arrangements.

Birth Control

The ability to have sex without pregnancy is an extraordinary development in human history (Critchlow 1996). Control of reproduction allows women to have sex with males who are attractive but unlikely to invest in children, leaving women free to pursue individual gratification without fear of harming children. It also allows men to have sex with women without fear that they will incur a paternal obligation.

Birth control tends to increase the likelihood that women will dissolve a relationship (Marcen 2015).

No-Fault Divorce

In many states in the USA today, divorces may be obtained without providing a particular reason for the breakup. Couples can simply agree to part, and the dissolution of the relationship is sanctioned by the state. In a study of the impact of no-fault divorce on divorce rates in all 50 states in the USA, Nakonezny et al. (1995) found that the number of divorces increased in all but six states after no-fault legislation was enacted. Of course, no-fault divorce is easiest when there are no disagreements over assets such as money and property or custody of children.

Prenuptial Agreements

Such agreements are common where one partner, usually the man, is wealthy. In effect, they

constitute an agreement in advance to dissolve the relationship under certain conditions. They provide some protection for the wealthier party and generally guarantee that if the less wealthy party, usually the woman, wants to dissolve the relationship, she and any children will not be exposed to poverty. Prenuptial agreements have commonly been initiated by the rich, but Marston (1997) makes the case for extending prenuptial agreements to all couples, regardless of their wealth.

Financial Independence of Women

Today many women can dispense with the need for investment by the biological father. The ability of women to make enough money to support their children gives them a vastly increased ability to leave unsuccessful marriages and an incentive to do so. According to a 2005 study (Milligan 2005), single women were the second largest group of home buyers in the USA in 2004. Divorce, delayed marriage, and financial independence are fueling this trend.

Alimony and Child Support

The availability of alimony and child support is another factor that contributes to the rise in relationship dissolution. These supports not only provide a source of income for the woman, but they may also serve to reduce a male's sense of guilt about initiating a breakup. On the other hand, fear of living in reduced circumstances due to alimony payments can deter men from dissolving a relationship (Zagorsky 2005).

Welfare for Women and Their Children

Women whose spouses don't or can't provide alimony and/or child support are eligible for government support. Welfare makes it possible for a poor married woman to initiate divorce without fear of penury. In the USA today, there is little reason to think that a fatherless child won't survive.

Decline in the Power of Religious Prohibitions

In many modern societies today, religious prohibitions against divorce and adultery have less force as a constraint on people's willingness to

abandon a marriage and on the propensity of both males and females to act on their desire to pursue extramarital sexual opportunities (Stokes & Ellison 2010).

Social Acceptance of Cohabitation

Possibly because of the decline in the power of religious prohibitions, living together without being married is increasingly accepted in many societies. Cohabitation was once thought to be a way of strengthening relationships because it allowed couples to get to know each other without the legal and social trappings of marriage, but Axinn and Thornton (1992) found that not only are there a high number of relationship dissolutions among cohabiting couples but those who married after a period of cohabitation also had a high divorce rate.

Unmarried couples in long-term relationships who break up don't get the advantages that have been built into the law to support and encourage marriage (e.g., custody, alimony, child support), but, as Axinn and Thornton's research demonstrates, there is more freedom for both partners in a nonmarital relationship, particularly if there are no children, and it's much easier for either partner to dissolve the relationship.

Custody

Some of the most bitter battles in the breakup of relationships today are fought over who gets the children for how much time (Ayoub et al. 1999). According to Wolman and Taylor:

...the contested child is faced with an extremely complicated set of conflicts and stresses arising from the interparental battle. Some of these problems include: (1) inadvertent or conscious involvement in marital hostilities; (2) parent-child role confusion and role reversals; (3) the stress of living in a highly volatile emotional climate in which one has little control over the outcome of events and a great deal at stake; (4) cognitive dissonance resulting from parents' presentations of radically different, competing views of reality; and (5) disillusionment, or dissonance between what children have generally been socialized to believe and what they learn to expect on the basis of their own experience. (Wolman and Taylor 1991, p. 406)

Conclusion

Human males and females, like most other mammals, have different reproductive strategies, and those differences can create tension, resentment, and anger that often lead to the dissolution of long-term relationships. Our hunter-gatherer ancestors evolved a social structure that gave individuals both the security of long-term relationships and a considerable amount of sexual freedom. Relationship dissolution was common and relatively easy. Children were cared for by the entire band, so parental breakups did not compromise their physical or psychological health.

Today, after thousands of years during which relationship dissolution was fraught with many difficulties and dangers, it has again become relatively easy. Modern societies provide fairly well for the survival and physical well-being of children but often less well for their psychological welfare when their parents break up (Wolman and Taylor 1991).

Reliance on the nuclear family – a unit that is subject to dissolution due to the vagaries of sexual attraction, love, and social and religious mores – puts many children at risk today, sometimes physically, often psychologically. The risk would be minimized if children were raised by a “band,” as they were throughout most of our existence as a species. Unfortunately, although many contemporary societies have made it easier for people to dissolve long-term relationships, they haven't fostered communities that can offer the broad adult support that the children of breakups often need.

Relationship Satisfaction and Commitment

Definition

Relationship satisfaction and commitment refer to the extent to which people are happy with and intend to maintain their intimate relationships.

Introduction

Throughout evolutionary history, humans evolved various cognitions, emotions, and behaviors that helped them to overcome the numerous adaptive challenges that they faced. Those cognitions, emotions, and behaviors, in turn, functioned to increase survival and future gene propagation.

Not only did such adaptive challenges include those associated with producing offspring, ancestral men and women also faced challenges associated with the ability to successfully rear offspring to reproductive age. Traditional evolutionary perspectives argue that one way humans overcame this challenge was by forming lasting pair bonds, or long-term, romantic relationships, which functioned to provide offspring with biparental care (Kokko and Jennions 2003). Indeed, individuals who were able to form lasting pair bonds likely produced higher quality offspring and experienced lower childhood mortality. This entry highlights the role of relationship satisfaction and commitment to the maintenance of such romantic relationships.

Relationship Satisfaction

Not all romantic relationships are ideally suited for successfully rearing offspring. There are numerous costs and benefits associated with every partnership, and relationships in which the costs outweigh the benefits may be reproductively maladaptive – that is, they may have negative consequences for offspring. Scholars have argued that relationship satisfaction may serve as a barometer of the ratio of costs and benefits associated with a given pair bond and thus the extent to which that pair bond meets evolutionary-based mating needs and desires (Shackelford and Buss 1997; Meltzer et al. 2014a; see also Kelley and Thibaut 1978). Indeed, evolutionary perspectives posit that positive emotions evolved to promote and maintain reproductively adaptive behaviors (Nesse and Ellsworth 2009), and relationship satisfaction may reflect the accumulation of those emotions in response to the relationship. Consistent with this perspective, recent evidence suggests that relationship satisfaction reflects the extent to which people associate their partner with positive versus negative affect (McNulty et al. 2013). Accordingly, partnerships in which the costs outweigh the benefits (and thus do not meet people's evolutionary-based needs) should be characterized by relationship dissatisfaction whereas partnerships in which the benefits

outweigh the costs (and thus meet people's evolutionary-based needs) should be characterized by relationship satisfaction.

Factors Influencing Relationship Satisfaction

Many factors can influence people's perceptions of their relationship costs and benefits. For example, the quality of people's relationship partners and the extent to which those qualities match their ideal partner qualities can influence relationship satisfaction. Although some rewards and costs likely involve evolutionarily novel partner qualities, many qualities likely reflect those associated with effectively producing and rearing offspring (Fletcher et al. 1999). For instance, both men and women are more satisfied with romantic relationships in which they have partners who meet the evolved desires of both sexes, such as sexual intimacy and physical health. Yet, the implications of other partner qualities are more sex differentiated. For instance, consistent with the notion that there are sex-differentiated preferences in long-term romantic relationships, women's relationship satisfaction appears to be particularly sensitive to the extent to which their partner provides enough resources (Rogers and DeBoer 2001), and men's relationship satisfaction appears to be particularly sensitive to the extent to which their partner is physically attractive (Meltzer et al. 2014b).

But relationship satisfaction also depends on people's own mate value, particularly as it relates to their partners' mate value. The mate values of long-term relationship partners are often positively associated due to assortative mating (see Shackelford and Buss 1997), and partners whose mate values are similar report higher levels of relationship satisfaction. When there are discrepancies across partners' mate values (that is, when one partner has a higher mate value than the other partner), in contrast both partners may be at risk for decreased relationship satisfaction (Shackelford and Buss 1997). Whereas the relatively lower mate-value individual may experience anxiety due to concerns that their partner may leave them for another potential partner of higher mate value, the relatively higher mate-value individual may perceive that they could

obtain more benefits from an alternative relationship with a higher mate-value partner.

Relationship Commitment

But satisfaction alone does not determine whether one remains in a relationship; the alternatives to the relationship also matter. Taken together, satisfaction and alternatives predict relationship commitment, which directly predicts remaining in a relationship (Kelley and Thibaut 1978). Specifically, people should remain committed to their relationships to the extent that they (a) are satisfied with their current relationships and (b) perceive that their current relationships provide more benefits (relative to costs) than their alternatives outside of those relationships might provide (Kelley and Thibaut 1978). Indeed, individuals who perceive that their relationship costs outweigh their relationship benefits, and thus experience lower relationship satisfaction, are typically less committed to maintaining their relationships; and individuals who perceive that the benefits associated with their relationship alternatives (e.g., other potential long-term partners, short-term relationships) exceed the benefits (relative to costs) associated with their current relationship are typically less committed to maintaining their relationships.

Not only does commitment directly predict remaining in a relationship, it can also motivate intimates to improve the quality of their relationships (see Rusbult et al. 2001). Accordingly, both men and women benefit to the extent that they and their relationship partners remain committed to quality relationships. Indeed, compared to less committed intimates, more committed intimates invest more resources in their relationships – resources that benefit their partners and their potential offspring – and attend less to attractive alternative partners, which reduces the likelihood of sexual infidelity.

Conclusion

Ancestral men and women would have benefited to the extent that they could maintain satisfying,

committed romantic relationships. Throughout evolutionary history, not only did those individuals who remained happily committed to long-term partners have increased sexual access that would have been associated with an increased likelihood of conception, they also invested more time and resources into their relationships that would have increased the likelihood of biparental care and thus offspring's future reproductive success. That is, relationship satisfaction and long-term commitment likely evolved to help people meet the needs associated with reproductive success.

Relationship Status

[Marital status](#)

Definition

It refers to the current position of a romantic relationship (preferably marital).

Introduction

Relationship is defined as “the state of being related” or “the state of affair between an individual with another individual(s) or environment” (Dictionary 2006). Similarly, status is defined as “position or hierarchical rank of an individual in relation to others” (Dictionary 2006). Relationship status often refers to the marital status (*state of being married or not married*) (Dictionary 2006). The relationship status can be single or married. Single relationship status refers to individuals who are either never married, socially separated, divorced, widower, or widow. Other relationship statuses refer to individuals who are neither single nor married. Often individuals who are living together (cohabiting) or committed for marriage but not married yet come in this category of relationship status. Certain individuals are not willing to disclose their relationship status due to personal reasons and prefer not to specify their relationship status. Relationship status also tells the sexual orientation of the individuals. Individuals often mention their sexual orientation (straight, gay/lesbian, bisexual) along with their relationship status. Individuals with casual relationships often refer to their status as single, but those in committed or long-term relationships seldom label their status as single. Men with “single”

relationship status are found to have higher testosterone level than those in long-term relationships (van Anders and Goldey 2010).

In a romantic relationship (particularly among the opposite genders), the concerns are usually gender specific. The relationship status might have a role in determining the concerns of men and women. The sexual behavior of men and women in a relationship too differs. Men often have willingness toward casual sex, whereas women often offer resistance for casual sex (Roese et al. 2006). Often, men in a relationship regret their inaction (i.e., not advancing in romantic relationships or losing romantic opportunities outside the current relationship) (Roese et al. 2006). In a romantic relationship, retaining the mate is an important and challenging task. Mate poaching is a threat to the relationship and people adopt various mate retention tactics to save the relationship (de Miguel and Buss 2011).

Relationship Status: Online Activities

With the advent of the digital revolution, people tend to focus more on online social networks. Association of online social networks has popularized the term “relationship status.” People often post their relationship status online. Relationship status has various personal as well as social implications. Posting the relationship status publicly (in social media), or discussing it publicly, too has many psychosocial implications. Evidences support that relationship status has huge influence on the activity of males on Facebook; however, it has little influence on the Facebook activity of females (McAndrew and Jeong 2012). Posting relationship status online is a form of self-portrayal as well as self-disclosure in public. Neuroticism, extraversion, and agreeableness direct an individual to disclose self, online (Seidman 2013). Relationship status of the individual influences online sexual behavior. Evidence supports that men and homosexuals (gays/lesbians) are found to be involved more in online sexual activities than women and straights (Albright 2008). Loneliness is found to have a positive association with various parameters of

Internet use (Matsuba 2006). Individuals, who are never married, separated, divorced, and in unstable relationships are more likely to experience loneliness and hence have higher probability of Internet use and online activities. Self-portrayal of relationship status online can be one determinant of intimacy seeking or avoiding behavior. Many people quote their relationship status to be “single” in the online social networking platforms to invite potential romantic relationships (Young et al. 2009). Similarly, nondisclosing relationship status online might have multiple implications like avoiding invites from opposite genders for a romantic relationship, hiding the ongoing relationship, doubt about current relationship or it may be due to social concerns.

Implications of Relationship Status

Evidence supports that stable relationship status is associated with better subjective well-being and greater life satisfaction (Dush and Amato 2005). As individuals move from an unstable relationship to a stable and committed one, the life satisfaction becomes better too (Dush and Amato 2005). Individuals who are single, are found to have lesser subjective well-being than those who are dating or in a stable relationship (Soons and Liefbroer 2008).

Relationship status not only influences the life of young individuals; elderly people are affected equally as well. A study attempted to evaluate the association of relationship status in elderly population with hospitalization in long-term care facilities and it was found that single (widowed, divorced, or never married) individuals possess the highest risk of hospitalization in long-term care facilities. Again, relationship status was found to be an important determinant of long-term hospitalization more so for men than women (Thomeer et al. 2016). It is seen that relationship status determines the likelihood of postretirement work. Men with a relationship often work in their postretirement period, whereas the reverse happens in cases of women (Settels and McMullin 2017). Relationship status not only influences the interpersonal relationship and

quality of life between spouses, it has impact on the mental well-being of their children. Children of mothers in unstable relationships have more than 8 times higher risk of development of mental health issues than those children whose mothers are in stable relationships (Hannighofer et al. 2017). Relationship status of pregnant mothers too influences the fetal well-being. It was reported that pregnant mothers, who have an unstable current relationship are more likely to have babies with small gestational age than those mothers with current stable relationship status (Steinberg et al. 2016).

Relationship status has a positive impact on life satisfaction as well as achieving remission from stress by causing structural brain changes in specific brain regions (left superior frontal gyrus and bilateral middle frontal gyrus) (Zhu et al. 2018). Relationship status seems to influence mortality risk. Individuals who are single have higher risk of mortality than those in a relationship (Scafato et al. 2008).

Individuals in a stable relationship often perceive their sexual relationship to be safe, secure, and stable. Stable relationship possibly gives rise to the belief of low risk of acquiring sexually transmitted disease. This reason might be responsible for low perceived risk of human papillomavirus (HPV) infection in women, who are in monogamous stable sexual relationships (or have fewer sexual partners). These women often resist or avoid HPV vaccination (Thompson et al. 2017). All these evidences support that relationship quality and stability are more important than relationship status for subjective well-being.

Evolution and Relationship

Relationship status can be seen from an evolutionary angle as well. It has been seen that pair bonding and romantic love has played a role in the evolution of the human race. Romantic love serves as a mode for commitment, which in turn helps in pair bonding of humans. The life history of humans says that this commitment gives an investment to rear children. These long-term pair bonds have helped in the evolution of social

intelligence and large brains. It was seen that romantic love is universal and it suppresses the need for search of other mates and also promotes better health. This leads to successful pair bonding. Phylogenetics suggests that monogamy goes back to the *Homo erectus*. The societal structure of modern humans has been dependent on this pair bonding. Even the metabolic requirements of large brains were dependent on pair bonding. Though there have been challenges to this proposition in the form of polygamy, divorce, infidelity, and arranged marriages, it has been seen that in the vast majority of the human culture the concept of romantic love and pair bonding remains true (Fletcher et al. 2015).

Understanding evolutionary background, enables us to conceptualize the factors that influence “stability of relationship”. Relationship alternatives that can be tempting can pose a threat to the commitment of the relationship. It has been suggested that not only do overt characteristics play an important role but also that hidden cues have a role as well. Evolutionary psychology gives new predictions regarding processes in the mind about increasing reproductive success. Research shows that levels of fertility in women have helped in describing characteristics that can be alluring for a prospective male partner and thus can also be a threat to long-lasting relationships. Thus, evolutionary theories of mating are also important in understanding the maintenance of long and stable relationships (Miller and Maner 2010).

Conclusion

Relationship status of an individual gives an idea about his/her social as well as psychological well-being. Relationship status can be better understood by knowing the quality and stability of the relationship.

Definition

The encephalization quotient is a between-species measure of relative brain size, operationalized as the ratio of actual to predicted brain mass for a given species relative to body mass. This indicator is used in comparative analyses involving different species as an index of cognitive ability.

Introduction

The comparative study of the neural substrates of cognition has demonstrated to be more elusive than previously thought, with epistemological and methodological caveats that create the conditions for tireless disagreements among researchers within and between fields of study for which neuroanatomical or brain activity measures are central variables or potential correlates. This entry will deal one such neuroanatomical measure, specifically the encephalization quotient.

Review

Overview

As neurological data that permit comparing across species or populations are difficult to collect at the physiological level (Striedter 2005), most studies use neuroanatomical measures instead of brain activity indicators. However, confounding factors such as body size have forced researchers to spend more time studying the relative validity and accuracy of diverse measurement approaches rather than analyzing the connection between neuroanatomical measures and cognitive and behavioral traits. Other confounds also exist: for example, even though such traits have been found to be evolutionarily labile, the distribution of neuroanatomical traits in primates and other mammals appears to have been highly conserved through phylogenetic history (i.e., with little lability within clades; Kamilar and Cooper 2013). Thus, it is argued that analyses to test hypotheses of coevolutionary ties between neuroanatomical and other variables should be conducted only after controls for the confound of phylogenetic history. This is a realization that has been increasingly taken into account in the last two decades, with findings from earlier evolutionary studies of the brain being more likely to be confounded with phylogenetic inertia.

Brain Size, Brain-Body Size Ratio, and Encephalization Quotient

Big brains do not necessarily mean complex cognition (e.g., such as in the case of blue whales, *Balaenoptera musculus*). Thus, brain size on its own is an inaccurate estimate of psychological processes. Brain-body mass ratio was proposed as a solution to the conundrum by endorsing the notion that the *proportion* of the volume of the brain in comparison to the rest of the body was the actual predictor of behavioral and mental traits (Kappelman 1996). Nevertheless, this ratio also created new problems; for example, it was found that smaller species exhibited larger brains in proportion to their body mass.

Jerison and Barlow (1985) proposed the encephalization quotient (EQ) as an alternative for estimating brain size while taking into account

body mass. The EQ was conceived as the observed brain volume divided by the expected brain size for a species of a particular body mass. Furthermore, it took into account the estimated surface of allometric growth of the animal studied (i.e., $2/3$ in the case of mammals) permitting the construction of the following formula:

$$EQ = \frac{\text{brain mass}}{(0.12 \times \text{body mass}^{(2/3)})}$$

Here, 0.12 is a constant of average growth. Thus, the emphasis of the measure lied neither on the actual brain volume nor in the ratio between brain and body size but rather on the brain size that was *expected* for an animal of a particular body mass. With this, animals of disparate sizes such as mice, rats, and baleen whales displayed expected EQ values in accordance with the mammalian regression line.

EQ exhibits important limitations however. Chief among them are the drastic differences on the steepness of the regression line after including few species in some analyses and removing them from others. Humans are arguably the clearest example of this, suggesting that the evolutionary pressures on brain size in the human lineage differed starkly from the average pressures that occurred throughout primate history. By settling on a regression line in the estimation of EQ, one is assuming that all taxa included have been subjected to similar regimes of selection for brain size evolution. Outliers (such as humans among extant primates) are eliminated in order to meet the assumptions of traditional statistical analyses and must therefore be considered separately. Running an analysis for an outlying datapoint, such as *Homo sapiens*, is by definition impossible. A solution, in order to examine humans' place in the EQ scale, is to consider it in the context of data from closely related extinct species such as *hominins* (Falk et al. 2000).

EQ is further limited by the fact that close taxa have similar body sizes. As a consequence, distantly related species will exhibit different scaling exponents. Thus by including or removing a clade, the computations of EQ and its correlation

to other variables can be altered depending on the degree of relatedness among the clades in question. To address this, Jerison and Barlow (1985) encouraged the construction of multiple regressions lines, where each line corresponds to a specific clade in the sample.

The Size of Specific Brain Regions as Alternative Neuroanatomical Measures of Cognition

Some researchers have endorsed the use of alternative neuroanatomical volume indicators and statistical techniques as proxies for intelligence (e.g., Shultz and Dunbar 2010), rather than simply using the suggested post hoc solutions to EQ. A current and popular option is to collect size data from a specific brain region hypothesized to be involved in complex cognition. Any confounding effects produced by the size of other areas can be removed when studying a single area of interest, either before or during analyses, for example, by creating a ratio of their sizes or entering the sizes of the other variables as control variables in a regression model. It is important to note that, if nonlinear relations are expected, the ratio approach should be avoided. It is important to note that in this approach, an assumption is made that brain evolution occurs in a modular fashion, where each region is hypothesized to be subjected to different selective pressures in the ecological conditions of each taxon (Barton and Harvey 2000). Hence, for example, studies interested in the neuroanatomical correlates of executive functioning and cognitive complexity have analyzed the volume of the neocortex across species.

Even though measures based on region size in comparison to overall brain volume have the benefit of automatically also controlling for the confounding effects of body size, using a raw estimate of the region's volume and residualizing the region's volume against body size itself (rather than against the size of the rest of the brain or of other regions) has also been proposed as an alternative (Deaner et al. 2007). A less strict alternative involves including body size as another predictor in the regression equation, achieving to control for allometric effects without restricting the proportion of variance in the sample.

Conclusion

The difficulty in comparing the predictive validity of these different methods of neuroanatomical measurement stems in part from the lack of reliable indices of nonhuman animal intelligence. In other words, there is no established standard measure of cognition to compare the neuroanatomical measures against. Major disagreements exist on what laboratory tasks or naturalistic observations of behavior to use as indicators of cognitive abilities (Reader et al. 2011), and debates still exist on whether such abilities should be conceptualized as independent or aggregated under a general intelligence factor (Burkart et al. 2016).

Alternatives to neuroanatomical volume measures exist for explaining cognitive evolution; however, they are comparatively underexplored, and testing their validity also suffers from this same limitation. Possibilities include gyrification of the cortex (i.e., the formation of circumvolutions that compact more gray matter in less volume), neuronal myelination and the associated speed of transmission, and neuronal and glial cell densities throughout the brain. While these variables are unlikely to fully explain interspecies variation in cognitive abilities, they should be considered *in addition to* neuroanatomical volume measures.

Definition

Evolved interests are attitudinal states that motivate us to act in ways that typically enhance the prospects for survival and reproduction. Modern moral systems and the state-sponsored legal institutions of enforcement to which they give rise suppress the fitness-diminishing instinctual interests that may have served to amplify the individual fitness of our hominid ancestors.

Introduction

Our behavior is rooted in motivational psychological states such as wanting or desiring. Such content-bearing attitudinal states, although quite

specific for each individual, can be more generally described under the rubric “evolved interests.” These seemingly ubiquitous interests include, but are not limited to, amicable relations with others (cooperation), aversion to harm (flight or fight), finding someone with whom to have and raise children (mating), acquisition of the resources required for survival (food), and a buffer against unforeseen or intolerable environmental conditions (shelter).

Now it is obvious (but important to note) that for one to want or desire something, such as decadent pastries or someone else’s spouse, it does not thereby entail that one has a genuine interest in indulging such appetites. Noshing on copious amounts of sweets is known to have deleterious effects on one’s health, and compromising otherwise good health is typically considered wrong. This is, for instance, why parents give out sweets to their children only on special occasions. Similarly, the revelation of an extramarital affair can have dire consequences ranging from costly divorce proceedings or social stigmatization to physical violence and even murder.

The Explanatory Promise of Evolutionary Psychology

The allure of a neo-Darwinian picture of human evolution is that it promises the conceptual resources with which to explain not only the alignment of motivational states and evolved interests but also the disconnect between them. Some stage-setting is in order here. It is necessary to state at the outset that *evolved* interests are determined as such only by way of reference to the fitness-bearing individuals that comprise a population in a particular environment. What is ultimately of interest to individual members of a population (or the genes that they carry), from the evolutionary perspective, is survival and reproduction. Any behavior or behavioral capacity that enhances prospects for survival or is conducive to increased fecundity is an evolutionary adaptation insofar as it has been naturally selected

for fitness-enhancement. Notice that the psychological motivations that prompt adaptive behavior can exhibit significant variation. It matters not whether one does the right (adaptive) thing for the wrong reason; consequences measured in terms of relative inclusive fitness are the evolutionary metric of importance.

How, then, can the occasional disconnect between currently held beliefs or desires and evolved interests be explained? Evolutionary explanations typically proceed by distinguishing between the selective pressures at work on our hominin ancestors during the Pleistocene and those facing modern humans. Small heterogeneous tribes of hunter-gatherers have given way to large stratified societies. These diachronic changes have placed very different demands upon human decision-makers. When our desires happen to contravene what is actually in our best interests, the mismatch is accordingly attributed to the dissimilarities in these environments. A well-worn example involves our craving for sugary or fatty foods. Such foods were rare or difficult to attain in ancestral environments and thus highly prized sources of energy. The brains of our hominin predecessors associated strong positive sensory responses with the intake of fatty or sweet foods, which promoted and reinforced the expenditure of additional effort to acquire them. In the developed world, however, calorie-rich culinary delights abound. Only with painstaking effort are we able to avoid overindulgence and many tragically succumb. This evolved interest is a critical factor in the causal story behind epidemic levels of obesity in First World Nations.

Morality as an Adaptation

Morality presents a particularly interesting and perplexing case for this evolutionary narrative about our evolved interests. With language comes a heightened ability to coordinate collective action, and there are undoubtedly great benefits (e.g., division of labor) that accrue from robust social organization. But, as evolutionary game theorists are fond of reminding us, there remains incentive to behave selfishly when it comes to

collective endeavors, the rewards of which are equally distributed (Maynard Smith 1982). If one's duplicity can go unnoticed, it pays to be a "free rider." Moral codes are deployed to encourage cooperation and license the punishment of those who would attempt to cheat a social system. Hunter-gatherer life was such that tribal members were often closely related to and quite familiar with one another. This type of social arrangement makes the evolution of cooperation more likely than it would otherwise be since there are repeated encounters among the members of a tribe and expectations of reciprocation remain fairly reliable. It is, in short, exceedingly difficult to shirk one's interpersonal duties and have such behavior repeatedly go unnoticed or unremembered. There would be a strong intergenerational incentive to teach, learn, and abide by moral codes for the group and individuals alike. In such an environment natural selection would tend to favor psychological capacities and neurophysiological mechanisms that function to encourage cooperation and other prosocial behaviors. Mechanisms like kin selection and reciprocal altruism could work in tandem with cultural transmission to effectively suppress selfish incentives.

As group size increases, however, a rational agent will become less likely to cooperate to secure the benefits of repeated direct reciprocation. Interaction between any two agents will on average be less likely and information regarding the character of any particular individual, whether attained via hearsay or recalled from memory, typically more unreliable. Furthermore, the extent to which individuals are genetically related dwindles. Large stratified societies are now commonplace. Accounts of genuine moral disagreement regarding what we should do and how we ought to live abound in these modern social arrangements. Whereas it was once in our evolved interest to abide by tribal morality because doing so increased the inclusive fitness of individuals, changing social environments since the Pleistocene apparently enable a decoupling of fitness and utility (Sterelny 2003). Competing normative prescriptions now proliferate among — *as well as within* — societies and the specter of rampant moral relativism looms large.

One way to restore social cohesion and resist defection from a moral code is of course to codify normative prescriptions in the garb of religious tradition. In many religious traditions, there is reference to the existence of deities. These supernatural figures often have the role of punishing, whether in this life or the next, those who would transgress religious mores. The prospect of such divine reckoning presumably provided yet another way to ensure social cooperation in accordance with accepted norms. Even if one's self-interested (free riding) behavior could escape the notice of neighbors and their retributive practices, eluding the ire of an omnipotent and omniscient deity is another feat altogether. A propensity to reify the divine might in this sense be depicted as a social adaptation insofar as it strengthens the tendency to cooperate among those who share beliefs. As an unfortunate but telling corollary, it also lends to more fervent disagreement when groups with dissimilar belief systems begin to cohabit, since they are all the more committed to the objective authority of their moral beliefs.

There are seemingly insuperable problems with invoking a deity to bolster the efficacy of a moral system. Most notable, perhaps, is a dilemma introduced by Plato in his dialogue the *Euthyphro*. He therein asks whether what is good (or right) is so merely because it is willed by the gods or whether the gods will it because they have some sort of insight into its being good. On the former horn, even what appear to be morally reprehensible acts would have been good had the gods seen fit to stipulate them. The good is thus by definition equivalent to what the gods will. If so, however, a believer must accept a tautology in place of a substantive theory of morality: If the good is that which the gods will and that which the gods will is good, then that which the gods will is that which is willed by the gods. This is an empty truism. The will of the gods becomes arbitrary rather than beneficent; the doctrine of the goodness of god is reduced to nonsense. Recourse to the latter horn of the dilemma fares no better. If the gods somehow determine what is good by way of divine reason or omniscient insight, morality must be independent from, and exist prior to, the will of the gods. Believers are damned to ponder why the

gods have chosen the moral principles that they have (Rachels 1986).

Somewhat surprisingly, an evolutionary account of morality faces a similar dilemma. Plato's query resurfaces in something like the following manner: Is morality as we know it the result of natural selection on a highly contingent species-specific set of conventions for ensuring social cooperation, or has natural selection endowed human cognition with the capacity to grasp objective moral truths? Even thinkers quite sympathetic to evolutionary moral psychology are split on the answer. Those who find the idea of objective moral truth suspect hold to the former alternative. Moral skeptics, for example, begin by pointing out that human origins are entirely neo-Darwinian and materialistic (i.e., explicable solely by reference to physical-chemical processes and other naturalistic phenomena). They contend that our moral standards and intuitions, even our consciences, evolved because they were effective survival devices. Morality helped to ensure cooperation, which tended to enhance the prospects for survival and reproduction. Survival devices are not, however, reliable indicators of the truth. Cognitive and perceptual mechanisms and the behaviors which issue thereupon need not be perfect. Even highly unreliable indicators of external circumstances can sometimes suffice for avoiding detrimental outcomes. Moreover, it seems as though humans have no other characteristics that can help in the discovery of moral truth. As a consequence of the foregoing argument, it is impossible for humans to discover or even make reliable progress towards moral truth (see discussion in Richards 2000, pp. 203–211).

Moral antirealists urge an even stronger claim that flatly rejects the existence of any objective moral truths. The most contentious premises are those which claim that (i) survival devices are not reliable indicators of truth and (ii) that humans have no other means by which to discover moral truths. For the moral realist who is sympathetic to a story of human origins along neo-Darwinian lines, it is not obvious that the opportunistic character of selective explanation should make us cynical about the prospect of moral truth (Fitzpatrick 2015). While traits or characteristics

are often selected for one purpose, traits might well be retained for other purposes or even changed during the evolutionary process. Perhaps we have the moral capacities that we do because they are conducive to truth, despite the historically contingent origins of such prosocial capacities. Natural selection accordingly “tracks the truth,” and being true (or closer to the truth) is what makes one moral scheme “better” or “more fit” than another. Those who hold true beliefs and theories are more likely to thrive. So, argues the moral realist, it is not out of the question that we have capacities that at least allow for the perception of moral truths.

Do moral standards or personal intuitions about right and wrong exhaust our moral insight? Here, too, naturalistically inclined moral realists think otherwise (Shafer-Landau 2012). At minimum, humans have the ability to reason. Evolution via natural selection has left us with certain cognitive inadequacies that systematically lead us astray. Research in behavioral economics under the heading “biases and heuristics” has revealed many of these. Among the best known is the susceptibility to confirmation bias (e.g., Wason’s selection task). We tend to search for, interpret, and preferentially recall information that favors preexisting beliefs, while neglecting relevant information that can undermine the veracity of our beliefs. More important to the moral realist, however, is that we have been able to discover such species-wide unreliability through the use of reason. Much of a formal education consists of alerting students to such biases and teaching them how to reason correctly in spite of these tendencies. Why should matters be any different in the moral domain? We clearly appeal to metaethical (justificatory) standards when assessing competing ethical claims. When moral intuitions give rise to unsavory or inconsistent implications, we recognize that something is amiss. If this does not qualify as a resort to reason, it is unclear what would.

Conclusion

While metaethical debate still rages, it is well worth reminding readers that it does so more

than ever within neo-Darwinian confines (e.g., under the auspices of evolutionary psychology or behavioral ecology). Inquiry into moral disagreement and potential resolutions must at least acknowledge evolutionary cognitive endowment. Perhaps the most promising aspect of this approach is that it includes an empirically testable element: the search for gene networks (or mental modules) associated with the propensity to believe in the objectivity of morality. That both an avowed moral skeptic/antirealist and an agent without so much as an inkling of metaethical commitment share the sentiment that physically harming an infant is morally repugnant and worthy of severe punishment makes it plausible that this propensity is “a collective illusion of the genes” (Ruse 2002; Joyce 2006). Metaethical views apparently make no difference to actual moral behavior in such a case. It is compelling testimony to the power of the propensity to objectify moral truth that even a moral skeptic/antirealist should instinctively feel this way (Stamos 2008, pp.168–175).

Common to the adherents of conflicting moral systems is the devout belief that their normative principles are the right or true ones. Most cling to the idea that moral truth is a matter of discovery rather than social construction. In the end, their (evolved) interest in doing so may prove to be more telling than the contents of their various axiological commitments.

In general terms, honest signalling theory seeks to explain what keeps animal communication an

honest and reliable indicator of health, condition, and genetic quality in the face of many incentives for deception.

Introduction

Many commentators on animal communication and human language evolution have suggested that several aspects of language can be characterized in terms of honest signalling theory. Granted, although the complexity of language and human social interactions make plausible the suggestion that human utterances may have many parameters that could conceivably be assessed by receivers, I nonetheless selectively focus here on the most evidence-based proposals current to the honest signalling literature. Namely, the particular honest signals to be reviewed here include three related areas of research: (1) voice pitch, (2) vocabulary size, and (3) unfavorable social reputation.

Human Language and Honest Signalling Theory

In human social interactions, there are many motivations for deception, as people want to make the best possible impression (to appear important, dominant, intelligent and trustworthy) while others want to know if they accurately and reliably signal and possess these qualities. As language is perhaps the most salient and elaborate of human signalling systems, many recent attempts have been made to characterize aspects of language according to honest signalling theory. In general terms, honest signalling theory seeks to explain what keeps animal communication an honest and reliable indicator of health, condition, and genetic quality in the face of so many incentives for deception (Searcy and Nowicki 2005). Although honest signalling will be described in fuller detail in the following discussion, for present purposes, I firstly define language here as the uniquely human biological capacity for complex vocal imitation – the ability to imitate complex multi-syllabic vocalizations – including the cognitive, anatomical, physiological, and genetic systems that underpin human speech (Fitch 2010).

Honest signalling is ubiquitous throughout the animal kingdom in many different competitive, and occasionally cooperative, social interactions. For instance, in animal mating competitions, males of the most superior genetic quality, health, or physical condition also tend to display the most exaggerated sexual ornaments and weaponry (Andersson 1994). The female peahen's affinity for the male peacock's large and showy tail is often cited as the prototypical exemplar of sexual advertisement, as the male pays a cost as an assurance of its honesty: only those peacocks of adequately high health, vitality, and genetic quality can afford the most exuberant, burdensome tails in the face of mating competition, female choice, and predation (Andersson 1986). Sexual advertisement, in this sense, is defined as an honest signal of genetic quality or social status which increases the probability of reproductive success (Searcy and Nowicki 2005).

That said, though honest signals are often found in cases of sexual advertisement, they need not necessarily be found solely within this context. By definition, the primary criterion for honest signals in animal communication is cases in which the interests of signallers and receivers conflict (Searcy and Nowicki 2005). Accordingly, evolutionary biologists typically associate honest signals with particular costs which ensure their reliability, generally grouped into two basic categories: receiver-dependent costs (i.e., those that reflect agonistic, mating, and social costs) and receiver-independent costs (i.e., those that reflect underlying physiology including production, development, and maintenance costs) (Searcy and Nowicki 2005). Although some have argued that the latter type of honest signal – sometimes referred to as an index – is a special case that can be explained without reference to a particular cost, other studies have suggested that index signals fit squarely within the conventional framework of honest signalling theory. For example, receiver-independent production costs would include the considerable time, energy, and increased predation risk of many vocalizations (e.g., calling frogs, singing birds, or roaring red deer as an indicator of body size, health, or genetic fitness) (Searcy and Nowicki 2005), while receiver-dependent social

costs would include the increased aggression due to badges of status (e.g., variable facial patterns in wasps as an indicator of social dominance) (Tibbetts and Dale 2004). For present purposes, I adopt this more conventional definition of honest signalling theory and presume that honest signals can often be associated with a detectable cost.

With respect to human language, many commentators have suggested that several aspects of language can be similarly characterized in terms of honest signalling theory. Granted, although the incredible complexity of both human language and human social interactions make plausible the suggestion that human utterances may have *many* parameters that could conceivably be assessed by receivers, perhaps more than most animal calls, I nonetheless selectively focus here on the most theoretically-sound, evidence-based proposals current to the honest signalling literature. Namely, the particular honest signals to be reviewed here will include the associated receiver-independent development, production and physiological costs of (1) voice pitch and (2) vocabulary size, as well as the receiver-dependent social cost of (3) unfavorable reputation.

More specifically, some have suggested that many suprasegmental features of language, such as voice pitch, may have evolved as an honest signal of sexual attractiveness, social dominance and genetic fitness, with concurrent costs including suppressed immune function as well as risky social and sexual behavior, due to the masculinizing effects of testosterone (Puts et al. 2016). Alternatively, others have proposed that vocabulary size may have evolved as an honest signal of human intelligence and should therefore be attractive to prospective mates, with concurrent costs including the effort necessary to amass a large vocabulary as well as the cognition required to store and retrieve words in memory – as a receiver-independent cost (Miller 2000; Lange et al. 2014; Oesch *in revision*). Lastly, others have argued that human honest signalling theory should emphasize social status and influence, with the concurrent cost including the risk of unfavorable social reputation in an information-based society – as a receiver-dependent cost (Silk et al. 2000).

According to this honest signalling proposal, reliable indicators of biological condition and genetic fitness may have evolved once a rudimentary system of protolanguage was already in place (Dunbar 2009). Although the original biological function of human language remains hotly debated, most authorities are nonetheless in general agreement that honest signalling is thought to be a secondary function – as it is for most animal communication – which evolved at a later stage in the evolution of language (Dunbar 2009; Oesch 2016; Oesch *in revision*). By analogy to a previous example, the original biological function of feathers was and likely continues to be for thermoregulation (and flight) (Bock 2000), in spite of the fact that iridescent peacock plumage nonetheless secondarily functions as sexual advertisement in mating contexts (Andersson 1986). The original biological function of language, it has been argued at least by some authorities, is that language initially evolved for social bonding in large human communities (Dunbar 2009; Oesch and Dunbar *in revision*). In the context of human language evolution, this distinction is often more technically referred to as the difference between *direct* and *derived* functions (Millikan 1984). In simple terms, the direct function generally refers to the primary adaptive significance of language (e.g., social bonding, cooperation, cultural learning), having deep ancestral origin and which thereby directly aided the survival and reproduction of the human species, relative to other ancestral hominids which did not evolve language (Oesch and Dunbar *in revision*). By contrast, the derived function refers to any secondary, more specialized adaptive function(s) of language (e.g., voice pitch, vocabulary size), having more recent ancestral origin (once some form of language was already in place), but which also contributed to the survival and reproduction of the human species (Oesch 2016; Oesch and Dunbar *in revision*).

Voice Pitch as an Honest Signal

The human voice is a rich and nuanced source of information for listeners. In addition to

functioning as the primary medium of communication in spoken language, in its nonlinguistic role, the human voice has the ability to convey biological information like sex, age, height and weight, emotional states, social dominance, and even social categorizations such as race (Puts et al. 2016). For example, the primary perceptual correlate of voice pitch, also known as the fundamental frequency (F_0), is approximately half as high in men as it is in women, thereby providing information relevant to sex determination (Titze 2000). Moreover, the sexual attractiveness of a particular voice may be related to a number of speaker-specific physical and social assessments. Human voice pitch, similar to other phenotypic traits relevant to mating, such as facial symmetry, may be a reliable indicator of condition and biological quality in humans (Puts et al. 2016). Attractiveness, as a general topic, is of further interest for many reasons, and one major perspective is that human physical attraction drives the selection of mate partners. For vocal, as opposed to physical, attractiveness, this theory is supported by a body of research linking vocal traits to human sexual dimorphism that have likely undergone intense sexual selection in humans (Puts et al. 2016). For instance, vocal attractiveness has been shown to be correlated with both body attractiveness and facial attractiveness in both men and women (Puts et al. 2016). That said, active debate and research currently exists as to whether the most important influence on such sexual dimorphism was due to intersexual selection (male and female choice of the opposite sex) or intrasexual selection (competition between members of the same sex for access to the opposite sex) (Puts et al. 2016).

Nonetheless, at a proximate physiological level of explanation, this consistent relationship between facial and vocal attractiveness, at least in men, is likely mediated by the masculinizing effect of testosterone across many dimensions of human genetics, development, anatomy, and behavior (Puts et al. 2016). Moreover, producing a low-pitched voice in men – due to differences in length and tension in the vocal folds of the larynx – is believed to be costly, since testosterone, which lowers male voice pitch during puberty, is

associated with suppressed immune function as well as risky social and sexual behavior (Puts et al. 2016). Low-pitched voice in men, due to its association with testosterone, may provide a reliable signal of immunocompetence and genetic quality, long-term health, physical strength, reproductive potential, and in traditional societies, reproductive success (Puts et al. 2016). In addition, both men and women use lowered voice pitch in order to assess social dominance and leadership behavior, as well as trustworthiness (Puts et al. 2016). For example, male corporate chief executive officers (CEOs) with deeper voices often manage larger, wealthier companies, while male candidates for elected public office with low-pitched voices also appear to have better election outcomes. Given these findings, it is perhaps not surprising that women generally prefer men with more masculine, lower pitched voices especially near ovulation, and when evaluating short-term, sexual relationships (Puts et al. 2016).

In women, high voice pitch may signal low testosterone and/or high estrogen levels. Moreover, women's voices are judged more attractive by men mid-cycle and voice pitch increases as women near ovulation when estrogen levels are high. Higher pitched female voices are further associated with attributions of femininity and youth, though they apparently seem to be more closely tied to femininity (Puts et al. 2016). In general, current research on men's preferences for vocal dimorphism in women has found that men prefer more feminine or higher pitched voices (Puts et al. 2016).

Apart from these relatively straightforward features of human mate choice, there is at least some suggestion that voice pitch may also be a reliable indicator of even more complex aspects of human sexual behavior, including conformity to community speech norms. For instance, at least one recent study has found that men may attribute high infidelity risk to overly feminized women's voices, whereas women may attribute high infidelity risk to overly masculinized men's voices (O'Connor et al. 2011). This suggests that voice pitch may be used as an indicator of sexual strategy in addition to underlying mate value. Accordingly, the aforementioned attributions may be

adaptive if they prevent cuckoldry and/or loss of parental and relationship investment through the avoidance of partners who may be more likely to be unfaithful (O'Connor et al. 2011).

That said, although some voice pitch features of masculine or feminine traits may reliably indicate positive attributions in the speaker, they may also, at times, reliably indicate negative attributions. For instance, masculine men are more likely to be attributed potentially antisocial traits, such as dominance and dishonesty. Men with masculine traits are also generally more interested in pursuing short-term than long-term relationships. In addition, men with high levels of testosterone have been shown to invest fewer resources in their partners and offspring. Taken together, these findings suggest that although some masculine characteristics are associated with traits that are desirable in a mate, such as long-term health, immunocompetence, and genetic fitness, other features may be associated with traits that are not so desirable in a mate, such as low parental and relationship investment.

Lastly, recent investigations to determine whether men and women can intentionally manipulate vocal attractiveness have produced equivocal findings, but unquestionably indicate that both sexes often modulate their voices when speaking to attractive members of the opposite sex. Both men and women often appear to intentionally raise their voice pitch in order to express confidence and intelligence. At a perceptual level, listeners should be further selected and/or learn to detect vocal modification, given that misattribution of speaker traits such as attractiveness, dominance, and intelligence can be costly to the listener. Evidence for this proposal is also equivocal: as listeners can often accurately discern deliberately modified speech, such vocalizations nevertheless also seem to positively affect listeners' evaluations of these traits, suggesting that even when detectable, vocal modulation can often remain effectual, at least in some contexts.

Such intentional modification of voice pitch has clear potential benefits. For instance, individual variation in voice pitch can potentially influence the mate choice decisions and social attributions made by others in the local

environment, such as success in a job interview and political voting behavior. That said, although humans may be able to intentionally modify vocal pitch to emphasize or deemphasize various acoustic traits with meaningful variation in some limited contexts, such modifications nevertheless fit squarely within the constraints imposed by the many mechanical and anatomical limits on coherent vocal production (Pisanski et al. 2016). In other words, while some deliberate modification may be possible at the margins, the consistent and reliable wholesale “faking” of these traits, universally across most contexts, seems unlikely.

Vocabulary Size as an Honest Signal

Although many current hypotheses have attempted to explain the evolution of language (Fitch 2010; Oesch and Dunbar *in revision*), few proposals are able to explain why humans have such large, expressive vocabularies. De facto, no other species apart from humans are able to take a finite series of elements – conservatively between 15,000 and 30,000 word families for an educated, native adult speaker of English – and combine them into an enormous pattern of possible arrangements, all of which carry well-defined meanings. Curiously, this quality is a puzzling feature of human language, as natural selection does not usually favor costly, wasteful, exuberant traits. In general, nonhuman primate societies typically manage complex social interactions with comparatively fewer distinct calls. Nonetheless, a plausible explanation of this apparent redundancy is that large vocabularies could be used to demonstrate intelligence, and by approximation, biological fitness to potential mates (Miller 2000). By comparison, female birds have been shown to respond to greater song production, song rate, and repertoire size produced by males of the same species, which also have greater lifetime reproductive success. Bird song repertoire size has been further suggested to be reliable indicator of age, learning ability, brain size, health, nutritional condition, intelligence, and general fitness. In humans, a large body of psychological literature has similarly found that intelligence has the

highest heritability of any adult cognitive ability and that positive correlations exist between general intelligence, symmetry, and developmental stability, suggesting that intelligence could be a reliable indicator of heritable fitness.

Moreover, both twin and genetic analyses have shown that expressive vocabulary at ~24 months is modestly heritable ($h^2 = 0.16\text{--}0.38$), while large twin studies have reported a steady increase in the heritability of language-related factors during development from adolescence ($h^2 = 0.55\text{--}0.66$) through middle adulthood ($h^2 = 0.70\text{--}0.80$) (Spinath and Gottschling 2015). In particular, adult vocabulary size has been noted to differ quite dramatically among people, is at least 60% genetically heritable (even though every word in an individual’s vocabulary is learned) (van den Berg et al. 2004), and has about an 80% correlation with general intelligence (Trzaskowski et al. 2013). Moreover, intelligence has been established as one of the single most important traits desired in a long-term partner for both men and women (Plomin et al. 2013). Studies have also found that people in long-term relationships usually have vocabularies of similar sizes (Plomin and Deary 2015). Further evidence for this hypothesis has shown that men do indeed use more low-frequency vocabulary in the presence of attractive women (Rosenberg and Tunney 2008) and that the display of low-frequency vocabulary is attractive to both sexes, especially in the context of long-term relationships, suggesting that vocabulary size is in fact a reliable indicator of heritable mental fitness (Lange et al. 2014; Oesch *in revision*). On the other hand, as few studies have been done to determine if low-frequency vocabulary can be modified in the same way as volitional vocal pitch manipulation, (i.e., whether or not low-frequency vocabulary can be “faked,” as a deceptive proxy of intelligence in the same way as vocal modulation), the potential context-specific nature of this trait remains an open question. Clearly, the answer to this question would be contingent on whether the manipulator was aware of the potential benefits from using low-frequency vocabulary, “knowing of” a particular word while being simultaneously unfamiliar with its actual meaning, and the listener being

savvy enough to recognize its out-of-context usage. In this case, deceptive use of low-frequency vocabulary could be effectual as a context-specific signalling device.

Reputational Consequences of Dishonest Signalling

In the animal communication literature, deception refers to the act in which the signaller (or speaker) may benefit from the breakdown of the normative relationship between the signaller attribute or referent and the actual nature of the external world, while the receiver (or listener) may incur a significant cost from this misrepresentation (Searcy and Nowicki 2005). In more informal terms, deception has been defined elsewhere as “the projection, to one’s own advantage, of an inaccurate or false image of knowledge, intentions, or motivations” (deWaal 2005, p. 86). Chimpanzees, for instance, have been observed using deceptive nonverbal signals in the wild, as well as deceitful sign-language mimicry in trained conditions (deWaal 2005). Of course, whether any such acts of deceit constitute deliberate or intentional deception remains an open question (deWaal 2005). Nonetheless, punishment and the enforcement of sanctions against uncooperative or deceitful behavior have further been reported to occur in several social species; for example, in social insects in social dominance contexts (Tibbetts and Dale 2004), in rhesus macaques who find food covertly and withhold calls of the discovery (Hauser 1992), and in geladas from cuckolded males (le Roux et al. 2013).

In humans, other commentators have similarly suggested that human honest signalling theory should emphasize social status and influence, with concurrent costs including the risk of unfavorable reputation in an information-based society (Silk et al. 2000). More specifically, some have argued that nowhere would this phenomenon be more salient among traditional and modern societies than in the context of honest linguistic communication, given the potential costs of unfavorable social reputation and implementation of

strict social sanctions against lying and deception (Oesch 2016; Oesch *in revision*). Indeed, given so many clear incentives to deceive, often in the interest of manipulating rivals, many investigating the evolution of language have questioned how linguistic communication can remain primarily honest in the everyday use of language (Fitch 2010). One possible explanation, as noted above, is the risk of negative reputation and/or social sanctions against lying and deception (Oesch 2016; Oesch *in revision*; Silk et al. 2000).

Some indirect support for this proposal seems to suggest individuals could be wary of the potentially unfavorable social consequences of lying. For example, research has revealed that individuals seem to be much more inclined to deceive when the potential stakes are quite high, as for example when attempting to advertise to prospective mates, suggesting a context-sensitive signalling device (Toma et al. 2008). For instance, one study of online daters in New York City found that 87% of men and 76% of women lied about at least one attribute in their personal profiles; men tended to increase their height, whereas women tended to lower their weights (Toma et al. 2008). Deviations from truth were generally quite small in magnitude, however, suggesting that individuals were at least partially aware of the possible social repercussions from being discovered as deceitful (Toma et al. 2008).

Furthermore, previous findings have also revealed that lying and deception are relatively rare occurrences in the general population (Serota et al. 2010). For example, Serota et al. (2010) found, in a sample of 1000 Americans, the average number of lies told per day was 1.65. Moreover, the distribution was highly skewed; 22.7% of all lies were told by 1% of the sample, and half of all lies were told by 5.3% of the sample. Studies conducted in controlled laboratory environments have obtained similar results (Abeler et al. 2012). Granted, although the finding that lying is infrequent does not necessarily imply concern over negative reputational consequences, it would certainly be consistent with this argument.

Moreover, recent experimental work has shown that dishonesty can and often does indeed have unfavorable consequences on a person's social reputation (Oesch [in revision](#)). For instance, in a recent vignette-based study of dishonest protagonists in a hypothetical courtship scenario, dishonest protagonists were rated significantly lower on a 7-point Likert scale on the personality dimension of reputation, in addition to the dimensions of intelligence, pleasance, warmth, sexual attractiveness, dating desirability, relevance, and prestige. In effect, deception was shown to be ineffective strategy, insofar as the lies are made public, due to lower ratings on reputation as well as various personality dimensions included in the study. Accordingly, the findings supported the hypothesis that the high prevalence of linguistically honest information, in the everyday use of language, may have emerged as a socially or sexually selected handicap. In other words, truth-telling may be an honest signal of prosociality, trustworthiness, and social status with respect to alliances as well as mate choice, with concurrent costs including the risk of unfavorable social reputation.

Finally, social psychologists typically characterize human deception according to four different types of lying: (1) *prosocial*, lying to protect someone, or to benefit or help others; (2) *self-enhancement*, lying to save face, avoid embarrassment, disapproval or gain an advantage; (3) *selfish*, lying to protect oneself at the expense of another and/or to conceal a misdeed; and (4) *antisocial*, lying to hurt someone else intentionally (Iñiguez et al. 2014). In many cases, it is often useful to distinguish between two general types of lies: prosocial lies of type 1 and antisocial lies of types 2–4. Of these two general types, it is widely recognized that antisocial lies are destructive of relationships, whereas prosocial lies often help to keep relations in good condition (Oesch 2016). Therefore, as with voice pitch, while some intentional acts of deception may be possible, and even adaptive, in certain contexts, the normative and successful application of this strategy across many different circumstances seems less likely (Oesch 2016).

Conclusion

In conclusion, current research indicates that language can be aptly characterized in terms of honest signalling theory and further described by reliable and deceptive approaches to human social interaction. First, it seems clear that many supra-segmental features of language, such as voice pitch, may have evolved as an honest signal of sexual attractiveness, social dominance, and genetic fitness, with concurrent costs including suppressed immune function as well as risky social and sexual behavior, due to the masculinizing effects of testosterone (Puts et al. 2016), as a receiver-independent cost. Second, there is also emerging evidence that vocabulary size may have evolved as an honest signal of human intelligence and is thereby attractive to prospective mates, with concurrent costs including the effort necessary to amass a large vocabulary as well as the cognition required to store and retrieve words in memory, as a receiver-independent cost (Lange et al. 2014; Oesch [in revision](#); Rosenberg and Tunney 2008). Third, it seems further clear that honest signalling theory may alternatively emphasize social status and trustworthiness, while simultaneously discouraging widespread deception, with the concurrent cost including the risk of unfavorable social reputation in an information-based society, as a receiver-dependent cost (Silk et al. 2000).

There also remains the open question of whether voice pitch, large vocabularies, and other fitness indicators can be used to deceive others into inferring an individual has better fitness than they do in actual fact. For example, it is certainly conceivable that dishonest individuals might attempt to exaggerate others' impressions of their intelligence by intentionally using large vocabularies in the presence of those that they want to impress. However, apart from the fact that adult vocabulary size is largely heritable (van den Berg et al. 2004), and therefore difficult to convincingly fake, the deceiver would have to: (1) be aware of the fact that low-frequency vocabulary is attractive in the first place and (2) convincingly use the words correctly and appropriately to

the situation. Given that most potential acts of deception probably do not consistently satisfy both these criteria appears to make this possibility unlikely (Oesch [in revision](#)). In addition, if deceivers do attempt to manipulate potential romantic prospect's assessments of their fitness through deception, we should expect individuals to have evolved some effective countermeasures against these misleading displays (Cosmides and Tooby 1992). Furthermore, as we have seen here, the potential reputational impacts, coming from any discovered acts of deception, make this possibility even more unlikely. Consequently, though it is conceivable such deception may be an effective strategy within short-term interactions, it is unlikely to be convincing over long-term relationships.

Reliability, Efficiency, and Economy

Definition

Reliability, efficiency, and economy are criteria for adaptations attributed to George C. Williams.

Introduction

In the classic textbook *Adaptation and Natural Selection* (and to some extent in his *Natural Selection*), George C. Williams (1992) provides an account for when a biological trait is an adaptation. Establishing such an account, for Williams, is a “matter of basic importance” (Williams 1966, p. 8), as it would help to properly distinguish between traits that constitute bona fide adaptations from traits that just happen to be advantageous to the organism.

(This was an important distinction for Williams, as he thought traits should be classified as adaptations only once all other credible alternative explanations have been ruled out (Williams 1966, p. 11).) This entry sketches the three criteria for adaptations – reliability, efficiency, and economy – that are generally attributed to Williams and then presents one way in which these criteria have been further discussed in the literature.

Criteria for Adaptations

For Williams, an adaptation is best understood as a “function,” designed for bringing about some “goal” (Williams 1966, p. 9). The goal, in this case, is to “promote the success of an individual organism” (Williams 1966, pp. 96–97). It is generally thought that Williams puts forward three criteria for when a given trait can be classified as an adaptation: reliability, efficiency, and economy (Cosmides and Tooby 1997; Buss 2015). Consider these in turn.

Efficiency refers to the idea that adaptations achieve their effects in a (near) optimal manner. So, if a given trait increases an organism’s chances of survival and reproduction, but does so in a (significantly) less than optimal manner, it is not to be classified as an adaptation: only if the trait is (near) optimal in the production of its effects should it be seen as an adaptation. For an example, consider the length of time male dung flies mate (about 35 min – Parker 1978). It is not unreasonable to think that this length of time maximizes the males’ expected reproductive success (Parker 1978). Given this, the dispositions that cause male dung flies to mate for about 35 min qualify as possible adaptations. By contrast, if the mating time of the males were significantly different from 35 min (i.e., significantly different from its optimal value), the mating dispositions of males should not be classified as adaptations.

Not only must a trait be efficient to count as an adaptation, the trait must also promote survival in a way that is *reliable*. A trait is reliable if it is found in most organisms within the population and performs “dependably in the contexts in which it is designed to function” (Buss 2015,

p. 16). Consider a scenario in which fleetness develops only in a small subset of springboks and does not effectively provide a means of escape from cheetahs; in other words, suppose cheetahs pose a significant threat to springboks as they can outrun most of the latter – and even those that could run faster than the cheetah often fail to do so (e.g., for lack of energy or agility). In this case, we should not regard this trait as an adaptation. However, if fleetness were to regularly develop in most springboks and provide a reliable means for evading predators, then it would satisfy the reliability criterion.

Lastly, for a given trait to count as an adaptation, it must be *economical*. That is to say, the trait in question must solve an adaptive problem in such a way that the benefits outweigh the costs. For instance, fleetness does not constitute an adaptation if springboks exert so much energy that they die of starvation every time they successfully escape from cheetahs. Note that this is not to say that adaptations must be *perfectly* economical (e.g., that springboks incur no cost whatsoever from evading predators) (Williams 1966, p. 204). All that matters is that these costs are *minimized* – not that they are zero.

At this point, a quick note of caution is in order. While the criteria of reliability, efficiency, and economy are often attributed to Williams (1966) (see e.g., Buss 2015; Cosmides and Tooby 1997), it is not clear that Williams actually subscribed to them (at least as they are commonly understood). Williams himself is mostly concerned with assessing the extent to which a given trait can be seen as designed, and he uses the above criteria (or related ones, such as precision) merely in an informal manner (Williams 1966, pp. 10–11). So, for example, he writes: “In this book I will rely on informal arguments as to whether a presumed function is served with sufficient precision, economy, efficiency, etc. to rule out pure chance as an adequate explanation” (Williams 1966, p. 10).

Given this, it may be better to see the criteria of reliability, efficiency, and economy as *inspired* by the work of Williams, rather than as actually *defended* by the latter. However, be that as it may, there can be no doubt that these criteria have proven extremely influential in the

evolutionary biological and evolutionary psychological literature. Furthermore, since it is the content of the criteria that is important, rather than who (first?) defended them, historical questions concerning the formulation and defense of these criteria will not be discussed further here. Instead, what is of more interest is to consider one of the ways in which these criteria have been further developed and analyzed.

Further Developments

One of the most important ways in which Williams’s criteria have been further developed concerns the literature surrounding optimality models as methods for identifying adaptations. For example, Orzack and Sober (1994) accept the outlines of the above remarks concerning efficiency, economy, and reliability, but then go on to refine and expand these criteria. Roughly, they argue that a given trait can be seen to be an adaptation only if a model *restricted to the operation of natural selection alone* (a) accurately (in a standard statistical sense) predicts the value of the trait, and (b) there are no significant phenotypic differences in individual organisms in this population (Orzack and Sober 1994, p. 370). In other words, Orzack and Sober (1994) are notable for making precise Williams’s idea that genuine adaptations should be seen to be traits that are (near) optimal in terms of efficiency and economy of operation and which reliably develop in the relevant population of organisms.

However, it is also important to note that Orzack and Sober’s (1994) account is not without its detractors. In particular, Brandon and Rauscher (1996) have argued that Orzack and Sober’s (1994) account does not take into account the possibility that *other restricted models* (e.g., ones restricted to the operation of drift) can also accurately predict the value of the relevant trait. Similarly, Godfrey-Smith (2001) has argued that a trait can be seen to be an adaptation even if not all members of a given population have it. For these reasons, the status of Orzack and Sober’s (1994) account – and of Williams’s criteria more

generally – must be seen as a matter of current debate. However, what also needs to be noted is that there can be no doubt that these criteria have sparked much important discussion and that they continue to be taken very seriously in evolutionary biology and evolutionary psychology (see, e.g., Buss 2015).

Conclusion

George C. Williams's criteria of adaptations sparked an ongoing discussion about the nature of adaptations and their role in evolutionary biology and related fields. While not uncontroversial, the criteria of adaptations generally attributed to Williams – efficiency, reliability, and economy – have undoubtedly contributed significantly to our understanding of adaptations and the nature of natural selection.

A system of faith and worship typically composed of animism of inanimate objects and sometimes of a superhuman controlling power that may or may not be a personal God or gods and with its own set of moral injunctions.

Introduction

Despite the wide array of both past and present cultures and the incredible variety among them, religion seems to be part of our evolutionary heritage (Schmitt and Fuller 2015; Wilson 2002). Granted, some religions are monotheistic whereas others are polytheistic, and some religions, although not all, believe in a high god creator of the universe. Nevertheless, despite this apparent variability, religions do share some near universal features. Explaining the existence of these beliefs has been a goal of the interdisciplinary field known as the cognitive science of religion, a field that encompasses both the evolutionary psychology and evolutionary anthropology of religion. The major question regarding the field is whether religion itself is a mechanism selected by natural selection to solve a particular adaptive problem, or if it is merely a by-product of a lion of different psychological mechanisms such as agency detection. This section will explore the main theories regarding the evolutionary origins of religion. It is important to bear in mind that specifics of different religions will not be

addressed. Instead, only near universal features of religion will be discussed.

Near Universal Features of Religion

When one hears the word “religion,” it is instinctive to think about Christianity, Islam, Judaism, Hinduism, or other of the most well-known religions. These are known as world religions, and they actually have more in common than meets the eye. Most cultures and their respective religions share a common narrative about the origins of humanity, invoke supernatural agents, signal in-group loyalty through organized public affirmation of religious beliefs, ascribe animistic agency to nonhuman, mysterious sources, and distinguish between morally sacred and morally profane thoughts, beliefs, and actions (Schmitt and Fuller 2015). Nevertheless, it seems not all of these near universal characteristics evolved simultaneously. We do not know if some of these are sufficiently ancient for biological evolution to have shaped them for a particular purpose. In other words, some religion-related adaptations may have evolved before the emergence of organized religion as we know it, whereas others are modern inventions (Kirkpatrick 1999). For instance, Peoples et al. (2016) found that animism was the oldest trait of religion across a wide sample of hunter-gatherer societies. Other traits such as belief in the afterlife followed by shamanism emerged shortly after and were still present in most societies. Ancestor worship, which appeared later, was no longer found in many of the societies studied. Finally, belief in high gods was the most recent and least common characteristic, suggesting that these were absent in early humans. This emergence of religious characteristics over different periods of time makes it even harder to distinguish whether some aspects of religion are indeed adaptations selected through natural selection to solve a particular problem, or if they are by-products of other psychological mechanisms. Given that the debate is still ongoing, this section will describe both stands on religion, that which argues

religious belief is an adaptation and that which argues it is a by-product.

Religion as an Adaptation: Society as Organismic

The main theory arguing for religion as an adaptation views religion as organismic (Wilson 2002). Religious believers often compare their communities to a single organism that can work similar to individuals in the harmony and cooperation of their parts. Simply put, religious groups may work like social insect colonies. Organisms are a product of natural selection that acquires properties that enable them to survive and reproduce through variation. If religious groups are organismic in this sense, particular groups may have evolved because their properties proved more adaptive than the properties from other groups.

For instance, imagine a flock of birds. Selection at the level of the gene would involve birds varying in the degree to which they alert other birds of approaching predators. An individual bird does not gain anything by alerting other birds of danger, unless the surrounding birds are kin and share genes with the caller. Instead, a hypervigilant bird may be detracted from feeding by spending more time scanning the horizon, and by drawing attention from predators. As a result, these callers are less likely to survive and reproduce than non-caller birds. Generations later, the remaining birds are the descendants of non-callers.

An organismic theory, on the other hand, would argue that a group composed of mostly non-caller birds could face possible extinction and that natural selection would favor groups of *callers* over groups of non-callers. In this case, suppose there are two different flocks. The first flock is the one described above, in which the new generation is mostly composed of selfish birds that will not alert others of predators. The second flock is formed of mostly callers, with a few non-callers. When danger comes, the first group will have few or no birds alerting. Even if there are a

few callers, chances are predators will get these birds first since raising an alarm makes them an easy, conspicuous target. At one point, the group will be out of callers to raise alarms, and the unsuspecting birds will become another animal's meals and go extinct. The second flock, however, has better odds at surviving as a group. Because most birds are callers, some will die when alerting others, but some will also survive and further reproduce. The "caller" genes will be passed on to future generations, and the flock will likely live on.

But how do flocks of callers and non-caller birds compare to humans and religion? First and foremost, it is important to remember that humans are social animals. Our ancestors would not have lived long had they not realized that cooperation was a reliable method to survive. To support this idea, Wilson (2002) mentions how current hunter-gatherer societies are strong units of selection and egalitarianism. Meat is usually shared among all members of the community, with the best hunter and his family getting no more meat than others. Additionally, it appears many hunter-gatherer societies do not have leaders, aside from those who have earned the respect of other members by being models of good conduct and advise. Such egalitarian utopia seems counterintuitive to the concept of the selfish gene, yet even members in these societies are likely to have selfish impulses. The reason why they do not act on these impulses is because they are effectively controlled by other members of the group, a form of guarded egalitarianism known as *reverse dominance*. In many animal groups, the strongest individual is usually capable of dominating any rivals, but in hunter-gatherer tribes, any individual who attempts to dominate the rest is likely to encounter combined resistance. Even the strongest individual would be no match for the collective strength of the group and could instead be punished for these dominance attempts. Examples of reverse domination range from gossip and ridicule to ostracism and assassination. With such costly consequences, individuals are better off by simply cooperating and following the group's social norms.

Mechanisms that promote the welfare of the group as whole without demanding extreme sacrifice from its members would further reinforce adherence to social norms. It is here where religion and superstitious beliefs come into place. Wilson (2002) describes the case of the Chewong, a hunter-gatherer tribe that resides in the rainforest of the Malay Peninsula and that functions on egalitarianism like many other hunter-gatherer societies. Equal distribution of food and resources is governed by a system of superstitions known as *punen* in which not satisfying an urgent desire results in calamity. Actions that may result in a state of *punen* include not inviting someone to share food brought back from the hunt, and not sharing gathered goods when these were obtained from far away regions or when these are scarce.

Belief in the *punen* system conveys great advantages, and it is probably not by mere coincidence that the actions that may result in calamity have to do with food sharing. If a gatherer had to go very far to obtain a resource, then such resource must be shared with everyone, whereas if the resource is close to the settlement, individuals are allowed to keep whatever amounts they gather on their own. Such rules make perfect sense from an evolutionary perspective; forcing others to share resources that can easily be acquired would not convey any advantages because anyone would be able to gather these anyway, whereas sharing resources that were hard to obtain increases the chances of survival for those individuals who would have never been able to acquire these goods by themselves. Additionally, if all members truly believe that calamity will befall those who do not share, then they are more likely to obey any injunctions imposed by the group.

Overall, fear in a higher, punishing force or entity ensures compliance and obedience. Groups with such altruistic beliefs like the Chewong would have been more likely to cooperate and aid each other than groups with selfish beliefs, and because cooperation in a hostile environment is essential for survival, tribes with selfish systems would have disappeared. In this sense, like a beehive that works as one single organism because all

its parts work together to ensure survival, religion serves as an adaptation that allows humans to function as a coherent whole.

Religion as a By-product: From Hyperactive Agency Detection to Mating and Attachment

Though an interesting theory, Wilson's (2002) proposal of viewing society as organismic and religion as an adaptation that allows groups to function as a whole is not an idea that goes unchallenged. Selection at the level of the gene rather than within-group selection is a major key idea in evolutionary studies. Furthermore, one must consider other possible explanations and assess which one can do a better job at explaining the wider array of phenomena that religion has to offer. As Buss (2002) states, "Explanations for some religious phenomena, such as rituals and rites, may fail to account for other phenomena such as piousness or prayer." In order for a religion-specific mechanism to have evolved, it would have had to solve a particular adaptive problem faced by our ancestors, yet religion encompasses such a diverse amalgamation of beliefs and behaviors that is highly unlikely that it is the product of a single adaptation. Additionally, as discussed previously, many features of religion are too recent to have been shaped by natural selection and thus work as an adaptation. Finally, any hypothesis on the evolutionary origins of religion should not assume the existence of yet other unexplained mechanisms. An argument that religion evolved to ameliorate fear of death begs the question as to why humans would be built to even fear death in the first place (Kirkpatrick 1999). Finally, as Tooby and Cosmides (1992) state, our cognition resembles a confederation of hundreds of functionally dedicated computers, each designed to solve one particular problem faced during our evolutionary history. There is not one single general purpose computer capable of solving several adaptive problems at once. It is unlikely that religion is *the* computer in charge of creating cooperative behaviors among social groups, solving humans'

fear of death, monitoring sexual conduct and reducing promiscuity, preventing immoral actions, and so forth. Instead, the idea that religion is a by-product resulting from numerous domain-specific psychological mechanisms is perhaps more plausible and could help explain the myriad near universals that were described at the beginning of this section.

Because our minds evolved to process the world in ways that are adaptive rather than truthful, our cognition is prone to the occasional systematic error. For instance, it seems humans come equipped with mechanisms for categorizing and reasoning about the natural world (Kirkpatrick 1999). These include reliably distinguishing animate from inanimate objects, invoking different principles of inference such as causal reasoning, and ascribing goals, desires, and motives to people and objects displaying certain patterns of motion. Sometimes, these mechanisms may be misapplied beyond their intended domains. For instance, humans tend to have what is known as a hyperactive agency detection device. This device allows us to assume agency in inanimate objects, which may have been adaptive during our Pleistocene years, as confusing a rattling branch for a snake and avoiding it did not present costs to survival, whereas ignoring a rattling sound could lead to death if such sound did, in fact, turn out to be a snake. It is generally safer to mistake an inanimate object for an animate one, yet when these mechanisms are taken a step too far, an individual may ascribe agency and even anthropomorphize inanimate objects. As mentioned previously Peoples et al. (2016) found that animism or attributing a soul to plants, inanimate objects and natural phenomena was the oldest and most common religious characteristic found across a wide sample of current hunter-gatherer societies. These findings suggest humans are particularly prone to assign some form of life or essence to objects.

Social exchange and kin-related mechanisms are also manifested in religious beliefs and practices. Ancestor worship, reciprocal altruism, promotion of social cohesion and cooperation, and subordination of individuals' self-interest to that of the group are other common characteristics of

religions (Kirkpatrick 1999). Worshipping dead ancestors reflects kin altruism, as the living attempt to help the dead in the afterlife by burying artifacts and possessions while asking for help and guidance with their own worldly affairs. Attempts to enforce altruism do not end there, as many religions promote prosocial behavior beyond blood ties through the widespread use of kinship terms such as calling other members “brothers and sisters” or calling a priest “father.” Promoting deities that monitor cooperation and altruism and punish those who do not abide by these rules may also be an encouraging method for promoting prosocial behavior.

Additionally, altruistic and kin mechanisms can be observed not only in how people interact with each other and with their ancestors, but also in how they interact with the supernatural forces that they believe control nature, be it a high god or other entity. If a deity is perceived as kin, then attachment mechanisms may become activated. Perceiving God as a fatherly figure or as a caretaker plays on the attachment system by which the caregiver is sought as a haven of safety, particularly during times of danger. If a deity is not perceived as kin, interaction with it should be guided by the same principles of reciprocal altruism. Such seems to be the case given practices in which individuals offer deities different forms of offerings (e.g., impressive and massive monuments, works of art, and a variety of sacrifices) with the intention of gaining favors (e.g., good harvests, military victory, a place in heaven) from these high-status forces. In general, supernatural beings across religions tend to resemble humans, albeit with some “super” characteristics added. Deities may be ubiquitous or have the power to control some aspect of nature, but they otherwise display the full range of standard human emotions, desires, and motives, which is why interactions between humans and deities operate under the same psychological mechanisms as interaction amongst humans.

One final mechanism worth mentioning that seems to come into play in religion relates to mating and controlling others’ sexual behavior. As Buss (2002) points out, religious doctrines

frequently target mating and sexual behavior. When it comes to sociosexuality, religion has tried to regulate aspects such as when conception should take place, the age at which intercourse should begin, how many sexual partners an individual is allowed to have, the moral standing of premarital sex, and so on (Schmitt and Fuller 2015). According to the reproductive religiosity model (Weeden et al. 2008), heightened religiosity is often adaptively used by religious groups to discourage sexual permissiveness. Discouraging unrestricted sex is beneficial for males in that it decreases the chances of being cuckolded, and it is also beneficial for females in that it helps ensure their husbands will not abandon their long-term commitments to themselves and their offspring. Several studies suggest a link between religiosity and measures of permissive sexuality. For instance, Strassman et al. (2012) found that religions that were stricter in forcing females to signal menstruation and had higher levels of mate guarding had higher chances of paternity certainty.

Another aspect of religion as a device for mating is that religious leaders are often males who hold power and resources, which are important for females when looking for mates. Buss (2002) explains that religious leaders use their power to gain preferential access to fertile women. In native Greenland, for example, a woman would be considered fortunate if the Angekokk or prophet offered his sexual caresses. Similarly, the religious leaders among the Tachtadshys in Lycia could have sexual intercourse with any women they fancied during the yearly religious assemblies, and virgins among the Zikris were believed to be cleansed if they had intercourse with the high priest. These examples show how religious leaders had better access to females than the average man, which in turn increased their reproductive success.

Conclusion

The evolutionary origins of religion are still unknown, and religion is composed of such a plethora of phenomena that it is hard to separate

one aspect from the other. Although it is tempting to believe religion is an adaptation, it seems to be involved in one too many aspects of the human psyche to have evolved to solve a particular adaptive problem. Additionally, several aspects of religion seem to have evolved across time, with some practices such as burying the dead emerging before others such as belief in high gods or injunctions on moral sexual behavior. If religion did evolve as an adaptation, it could be possible that later components (e.g., belief in a punishing deity to ensure compliance to norms imposed by the group) were added to it because humans realized the value in them.

Definition

Mental representations of rites, tenets, and supernatural agent concepts derived from psychological processes and cultural inputs.

Introduction

Religious beliefs are both a product of natural selection and cultural evolutionary processes. Aspects of our evolved psychology, including certain cognitive by-products, underlie counterintuitive beliefs and supernatural agent concepts. Combinations of religious beliefs spread through competition between groups over the course of human history. Gradually, combinations of supernatural beliefs, tenets, and rituals that were increasingly effective at instilling deep commitment, reinforcing group solidarity, and sustaining large-scale cooperation became prominent among human societies (Atran and Henrich 2010).

Supernatural Agents and Counterintuitive Beliefs

Belief in supernatural agents plays a central role in both religion and religious ritual. Religions often invoke supernatural agents to reinforce values and moral principles, and to deal with distressing existential anxieties, such as loneliness, calamity, and death. Supernatural agents come in many shapes and sizes; there are malevolent and predatory deities as well as benevolent and protective ones. The cognitive mechanisms underlying the perception of agency act as a precursor for supernatural agent concepts, which are then modified by cultural transmission (Atran and Norenzayan 2004). Yet, what makes certain religious beliefs so memorable, especially beliefs concerning supernatural agents, is that they are *minimally counterintuitive* – they subtly violate our expectations about the world (Atran 2002; Atran and Henrich 2010).

Religious beliefs are counterintuitive because they violate universal expectations about how the natural world works. Counterintuitive concepts facilitate the recall and transmission of cultural information and also reinforce the underlying knowledge that can be inferred from them (Atran and Henrich 2010; Atran and Norenzayan 2004). The inclusion of a few minimally counterintuitive elements gives a story an advantage over other stories with either no counterintuitive elements or an overabundance of counterintuitive elements by

making the story more memorable for the learner (Atran and Norenzayan 2004). For example, the presence of a few counterintuitive concepts in a narrative, even within a list of otherwise ordinary concepts, improves memory recall for the entire narrative or list (Norenzayan et al. 2006). This suggests the existence of a “sweet spot” for the inclusion of counterintuitive concepts; there is an optimal balance of how much these concepts conform to and violate our intuitive assumptions about physical, biological, and psychological phenomena. That is, the presence of an optimal amount of such concepts can confer a mnemonic advantage to a set of beliefs – increasing their transmissibility. As far as *minimally counterintuitive* supernatural beliefs are concerned (e.g., belief in supernatural agents), they must be outlandish enough to capture attention, but natural enough to still make sense. Religions further propagate counterintuitive beliefs through ritualistic behavior, music, dancing, and other rhythmic coordinations of affective body states.

Cognitive mechanisms underlie supernatural agent beliefs (gods, ghosts, ancestor spirits) as evolutionary by-products. Natural selection did not, in all likelihood, select for the capacity for supernatural beliefs per se, but rather selected the underlying psychological processes involved with the perception of agency. Agency-detection mechanisms once served other adaptive functions (e.g., predator avoidance, identifying other humans) and have been repurposed by cultural inputs to incite supernatural concepts. Because of its utility in helping ancestral humans to overcome recurrent evolutionary obstacles, such as the threat of predation, agency-detection is a prominent psychological mechanism and is biased toward over-detection (Sanderson 2008). As a result, humans have a strong tendency to over-perceive agency and extend these intuitions about agency to many features of the natural world, such as the sun, elements, and other aspects of the environment. That is, humans often infer agency in natural processes where natural explanations are not available or not understood (e.g., weather patterns, lunar cycles, shifting tides; Atran and Norenzayan 2004; Sanderson 2008). Counterintuitive beliefs in supernatural agents (i.e.,

by-products of psychological adaptations and folklore) set the stage for the creation of powerful deities and moralizing high gods.

Moralizing High Gods

Beliefs in *moralizing high gods* are the product of psychological processes that facilitate belief in supernatural agents, coupled with cultural evolutionary processes that favored cooperation-enhancing beliefs. By the end of the Pleistocene (roughly 13,000 years ago), humans began transitioning away from seminomadic hunter-gatherer groups, coalescing into larger, sedentary populations in response to the advent of agriculture, population growth, intergroup competition, and warfare. These developments introduced somewhat evolutionarily novel challenges to humans living in large-scale groups, who now faced difficulties in coordinating behaviors among participating individuals, monitoring the actions of group members, preventing free riders from exploiting other group members, and facilitating large-scale group cohesion. For civilization to accommodate these new population constraints, it was necessary to invent and enforce beliefs in moralizing high gods that punished noncooperation and defectors within groups (Shariff et al. 2011). The central features of religions, such as moral guidelines, traditions, and the belief in one particular god or a specific pantheon of gods, have proliferated due to competition between different cultural groups, who each spread their respective religious beliefs and practices concerning moralizing high gods.

Costly Displays and Rituals

Rituals are a form of costly display that facilitates commitment to group ideologies, religious beliefs (e.g., belief in moralizing high gods), and shared values that promote solidarity and cooperation within groups (Atran and Henrich 2010; Atran and Norenzayan 2004; Henrich 2009). Costly displays can encompass a wide variety of complex, coordinated behaviors – from music and dance to

body modification, self-mutilation, and sacrifice. Such behaviors are “costly” because they are often time consuming, energy intensive, or dangerous. Though these behaviors may seem wasteful, harmful, or superfluous to an outsider, engaging in costly ritual displays confers an overall benefit to both the individual and the group by signifying commitment to a belief system and promoting group cohesion between individuals. These honest signals of commitment also encourage the adoption of supernatural beliefs, values, and customs that define a group’s culture.

Rituals both encourage and require the involvement of other group members and facilitate commitment to beliefs that promote group benefits, resulting in large-scale cooperation and group solidarity. Rituals promoted success in competition between other religious groups, because religious groups that engage in costly ritual behaviors bolster group cohesion. Religious groups with more costly rituals were more likely to survive over time than religious groups with fewer costly rituals (Henrich 2009). Differential group survival yielded a greater number of costly rituals across different competing religious groups. Rituals reinforce religious beliefs that manipulate our psychology to facilitate solidarity and commitment to the group, which in turn encourages group success (Atran and Henrich 2010; Henrich 2009).

Conclusion

Religious beliefs arise from a combination of evolved cognitive mechanisms, commitment-inducing rituals, and cultural evolutionary forces driven by competition between groups. Minimally counterintuitive beliefs in supernatural agents are by-products of our evolved cognitive mechanisms that create expectations about the natural world and cognitive adaptations devoted to the perception of agency. Cultural evolution, driven by competition among groups, spread such counterintuitive beliefs, rituals, and norms that ancestrally conferred an advantage to groups that adopted them. Civilization emerged with both commitment-

inducing rituals and the belief in powerful supernatural agents, such as moralizing high gods. Large-scale societies tend to incorporate beliefs in omnipotent supernatural agents that monitor and incentivize behaviors (e.g., rituals) that promote cooperation, strengthen faith, and facilitate solidarity in response to external threats. The wide variety of religious beliefs, rituals, practices, and institutions that we see today spread over time due to their ability to surmount the challenges posed by competition with other cultural groups and to sustain large-scale cooperation.

Different religions have provided their followers with advices regarding reproduction, advertising both quality and quantity strategies in producing offspring.

Introduction

“The only purpose, the real purpose of every communion in love is the procreation, the birth of a child, although people who are in love are unable to conceive the nature’s treacherous way, casting over the actual act a shining veil”

Arthur Schopenhauer

Why do religions tend to “teach”? Irrespective of religions’ ecological origin or their philosophical foundations, almost all religions have specific teachings. Evolutionary psychology of religion may provide an insightful analysis of religious teachings and their social function in different settings. The universal tendency toward religious beliefs has remained a genuine puzzle for evolutionary scientists. The current consensus among many evolutionary psychologists is that religion originated, as a by-product, from the interaction of several evolved psychological mechanisms

(Atran 2002). This explanation may be applied to all religions and reflects an inherent component of human nature. All religions have specific (and sometimes quite strict) rules and teachings ranging from food taboos to sexual advices.

One of the universal aspects of religious teachings is reproduction. Almost all religions have sets of rules about reproductive behavior. Aside from exceptions and special circumstances, the religious rule of thumb is “the more, the better.” There are various verses in religious texts that encourage heterosexual marriage and subsequent reproduction in large quantities (e.g., Bible, 1:28). As a result, most religions are said to take a pronatalist standpoint (i.e., promoting human reproduction). Religions would promote child-bearing and parenthood as desirable for social reasons and to ensure the continuance of that very religion. There are numerous teachings and incentives for religious people to reproduce, for example, children are considered *a gift from God*. There are controversies regarding different religions’ stands on abortion and contraception (Ekmekci 2016); however, most religions limit or prohibit these practices, which is consistent with pronatalism.

In many traditional African religions, bearing a large number of children fulfills one’s mandatory duty to ancestors and indicates that those who produce large numbers of children have been favored by their ancestors (Caldwell and Caldwell 1987). Strong stigma is attached to childlessness, which is viewed as a punishment imposed by the gods or their ancestors on evildoers. Since women would be primarily blamed for the failure to produce offspring, mothers, in these cultures, might be privileged with particular status for giving birth to a large number of offspring. However, large numbers of children would lead to individually less buttressed offspring who are at higher risk of survival, so religions do not always encourage a large number of children, that is, fewer children with higher quality are also important for a religion to flourish and prosper (Atari and Chegeni 2016). In other words, religions teach both “quantity” and “quality” strategies in reproduction. In

terms of life history theory (see Del Giudice 2009), organisms have evolved to apportion their metabolic resources in an adaptive manner across the lifespan. For example, some species (e.g., humans) apportion most of their metabolic resources toward a few offspring that abundantly receive parental care; however, other species (e.g., cockroaches) allocate most of their resources toward the production of many offspring that receive little parental care. This trade-off, often operationalized as *number* versus *survival* of offspring, arises because parents have limited amount of resources to invest in reproduction. Neither strategy is better or worse than the other, as each has its own advantages and costs.

Evaluation of the impact of religious teachings on reproductive behavior may be better understood if classified into two levels of analysis: (1) the societal level and (2) the individual level. Religious teachings’ influences at a societal level are usually examined by demographers. At this level of analysis, religiosity of a society is linked to its fertility pattern and population. At the individual level, however, one’s extent of religiosity and its intrapersonal manifestations on reproductive behavior is analyzed, usually by psychologists.

Religious Teachings Regarding Reproduction at Societal Level

Generally, specific teachings to directly influence the proximate determinants of fertility are most typical of *the religions of the book*: Christianity, Judaism, and Islam (also known as *Abrahamic religions*). Research attention has largely focused on the teachings of these religions regarding contraception and abortion, the most notable proximate determinants of fertility in many modern societies. In short, these religions take a pronatalist standpoint and set restrictions on at least some of these fertility-related practices. The Roman Catholic Church took the clearest stand in forbidding most forms of contraception and any recourse to abortion (Noonan 1986). Yet, other

Christian denominations have gradually moved toward more relaxed perspectives on the issue of contraception while maintaining strong opposition to the practice of abortion. In Judaism, a somewhat similar process has occurred. Yet, Orthodox groups still uphold strict regulations on these issues. Abortion is considered sinful as it interferes with the *creationistic* ideology of monotheist religions.

The reproductive teachings of Islam seem a bit more complicated than those of Christianity and Judaism. Opposition to abortion and to at least some forms of contraception, particularly sterilization, has been expressed by many Islamic leaders (Hoodfar and Assadpour 2000). A baffling aspect of the Islamic teachings corresponds to the differences between the teachings of Islamic leaders and the lay perceptions of the Muslim (Underwood 2000). While analyses of religious writings and even surveys of religious leaders suggest general approval of fertility control, several Muslim populations have reported religious reasons for not practicing contraception (McQuillan 2004; Wusu 2015). These seemingly paradoxical findings point to the importance of examining the official position of Islam on such controversial topics.

Frequent emphasis on the importance of the family and a positive representation of large families may perpetuate higher fertility and lead religious individuals to believe that the practice of family limitation is contrary to God's will (McQuillan 2004). Islamic Revolution of Iran in 1979 showcases the manipulation of religious teachings and religious fertility policy by religious leaders. Just after the revolution, religious leaders strongly encouraged fertility by referring to religious texts and postulated that "the generation of the Islamic Revolution" should be multiplied; however, concerns with overpopulation stimulated the leaders to discourage large families in 1990s and early 2000s (see Atari and Jamali 2016).

Many religions have articulated other guidelines that have the potential to increase or limit fertility rates (i.e., stimulate "quantity" or

"quality" strategies). One example involves teachings regarding entry into sexual mateships. Limitations on minimum age of entry into mateships, number of spouses, and entry into subsequent sexual relationships after widowhood or divorce are typical of many religions. The second example involves prohibitions regarding sexual activity outside the officially recognized mateships. A third, less frequently discussed, example (McQuillan 2004) involves issues of sexuality within marriage. A number of religions have detailed rules concerning the timing and frequency of sexual relations between spouses.

Religious Teachings Regarding Reproduction at Individual Level

How can one's religiosity affect his or her reproductive behavior? Actually, that is a good research question which has received less attention than it really deserves, particularly from an evolutionary theoretical perspective. The relationship between reproductive strategy and religious beliefs is a vibrant field of investigation (Gorelik and Shackelford 2016; also see Fieder and Huber 2016). In very general words, individuals more strongly affiliated to religion have, on average, more children than less religious ones. One of the most notable evolutionary theoretical works on the association between religiosity and reproductive behavior is the reproductive religiosity model (Weeden et al. 2008).

A central claim of the reproductive religiosity model is that one of the primary functions of religious groups is to help tip the balance of the risks associated with monogamous sexual relationships (e.g., cuckoldry for men) in favor of high-fertility strategies. Individuals who pursue such monogamous strategies need increased assurances of commitment from their marriage partners. Religious individuals seek honest assurances by embedding themselves within sexually conservative communities that increase the social costs of, and reduce opportunities for, promiscuity. Religious groups do not simply show

disapproval for promiscuity; they express moral condemnation. Moralizations of this sort impose social costs on those who are noncompliant, damaging their reputations and ostracizing them. Moralizations of this kind serve not only to manipulate the cost–benefit equations for followers of the religion but also to discourage those with competing, disruptive strategies from affiliating with the group. Moreover, religious groups usually do not limit their moral enforcement to their own members but work to impose sexually conservative norms on their society, sometimes by organized political efforts (Weeden et al. 2008).

The reproductive religiosity model is consistent with suggestions by Buss (2002), in that they raise the possibility that people may be attracted to or repelled from religious affiliations by the fit between long-term reproductive strategies and traditional family morals and by the social support provided by religious groups. Atari and Chegeni (2016) found that religiosity is positively correlated with the desired number of children in a sample of young Muslim women, which is line with empirical findings of Fieder and Huber (2016) and Weeden et al. (2008).

Conclusion

Religions have provided their followers with a set of pronatalist teachings on why, when, and how of producing offspring. Importantly, religions seem to advertise both “quantity” and “quality” strategies because these strategies are responsive to different evolutionary problems and are required for a population to be fruitful and multiply. Two levels of analyses were discussed: societal and individual. At a societal level of analysis, demographers examine the role religiosity on fertility patterns of large populations. *Abrahamic religions* present specific pronatalist teachings regarding high fertility, in addition to restrictions on contraception and abortion. At an individual level of analysis, psychological mechanisms linking religious beliefs and reproductive behaviors are investigated. Individuals who score higher

on religiosity often desire (and produce) larger numbers of children.

Formalizing Strategic Interactions.

Introduction

In prisoner's dilemma, and its group-level version – public goods – players face a nearly identical problem of exploitation by free riders or defectors. Product-services like TripAdvisor, Airbnb, Uber, etc., all rely on continued feedback from their users to produce and share vital information in a game-theoretic format. These businesses are somehow able to dodge the free-rider problem that has puzzled economists for decades. While they may seem like commonplace practices to a customer, the underbellies of these large markets reveal subtle and sophisticated architectures interacting with behavioral research. A quick step back into the theory may help formalize why this is worth investigating.

Game Theory and Its Behavioral Ally

Game theory presents a set of powerful mathematical frameworks that has wide-ranging formal applications from genetic strategy, couples' dating scenarios, to international commerce and warfare. For example, game theory explains nuclear warfare where two equally armed players achieve a state of Nash Equilibrium preventing confrontation as well as disarmament (Lakoff 2007).

However, one common criticism of game theory (despite producing 12 Nobel laureates) is that it does not fully predict real-world observations, especially those involving human players. One potential explanation for this weak predictive power may be that most mathematical models assume “rationality” of players, whereas human players systematically violate mathematical and economic rationality in game-theoretic decisions (see Camerer and Lowenstein 2004).

Behavioral game theory examines human players' decisions in game-theoretic interactions, attempting to unlock psychological factors that

may explain the apparent disconnect between purely mathematical game-theoretic models and real-world human interactions (Camerer 2003).

Prisoner's Dilemma and Public Goods

Prisoner's dilemma (PD) was one of the first games to reveal the power of game theory in explaining seemingly puzzling phenomena (Davis and Holt 1993). PD formulaically explained why individuals and/or groups of individuals would actively make decisions that made them ultimately worse off. Alternatively, PD can also be applied to analyses of choices between selfish and socially desirable behaviors and conditions that influence individuals to choose in a specific direction.

In the basic form of PD, two individuals decide whether to cooperate or defect, leading to specific and known outcomes (C, D, W, and S; see below). Each individual decides independently and is blind to the other's choice. However, final payoff for each individual is ultimately contingent on other player's choice. If both players cooperate, each is better-off (C) than if both defect (D). If both players choose differently, the defector gains significantly more (W, winner's payoff) than the cooperator (S, sucker's payoff) (Table 1).

Outlining the mutual payoff matrix makes it clear that assuming player rationality (a common assumption in economics), it is always better for individuals to adopt a "selfish" strategy (Nash Equilibrium), therefore foregoing the mutually beneficial outcome. This discovery was quickly used as a justification for both rational and pure selfish behaviors in social life (for review, see Caporael et al. 1989), ignoring both the structural and generalizable qualities of in-game choice.

Repeated or Iterated Prisoner's Dilemma,
Table 1 Simple PD outcomes matrix

Player 1	Player 2		
		Cooperate	Defect
	Cooperate	C, C	S, W
	Defect	W, S	D, D

Note: $W > C > D > S$

Dawkins' selfish gene theory (1976) was and is often incorrectly implicated in these justifications despite his clear discouragement of it. On the other hand, opponents of this view often cite the thousands of experiments with actual human players that consistently defy rational self-interest (Camerer 2003). Current academic debate explores the reasons why humans seemingly violate expected rationality.

An extension of PD to a group-level interaction with N players is the public goods game (PG) (for other interpretations, see Kuhn 2014). PG is arguably more directly social as it formally models several real-life social interactions such as a group of individuals acting to conserve a visibly exhaustible resource or groups facing a trade-off between resource consumption and environmental conservation, etc.

Of the N players, each (i) has assets worth a_i from which they can contribute resource r_i ($r < a$) toward a shared good valued at v_i . Thus, any given player i 's payoff can be calculated as

$$a_i - r_i + v \left(\sum_k r_k \right) / N$$

This reveals that the economically rational strategy (payoff maximizing) for any player is to not contribute anything, regardless of what others do $r_i = 0$ (when $v < 1/N$). But does this translate to real life?

Evolutionary Mechanisms May Explain Game-Theoretic Violations

Individual user payoffs for services like TripAdvisor resemble PG. Individuals who use the service can leave feedback and tips for other users. This is the resource (r_i) they contribute for others to benefit from which includes their time and effort which are limited assets (a_i) in writing the review into the pool of reviews (v) which is a shared good. It is important to note that while individual expends time and effort, no promise of payback is given. Such a scenario dictates that no individual should ever leave a review ($r_i = 0$) and the survival and success of such a system

should therefore be very difficult if not impossible to achieve as it heavily depends on group-level cooperation between independently operating individuals.

So far, the TripAdvisor comparison shares the structure of formal interactions and the outcomes with PG, but there is one important difference. TripAdvisor offers subtle yet powerful *socio-evolutionarily salient rewards* to individuals who provide reviews, namely, individuals receive *peer appreciation* in return for reviews and tips that others find useful. Reviewers also build *reputation* and *social status* by accumulating reviews and continuing to build their profile. It is therefore theoretically arguable that traditional PD and PG analysis suffers from a lack of incentives that are present in the real world. Specifically evolutionarily salient incentives can be particularly powerful in shaping decisions. This could be one possible explanation behind the theoretically unlikely success of TripAdvisor, especially since various other services like Yelp and Wikipedia use a similar model. Evolutionarily salient incentives then can foster cooperation in PD and PG.

To Cooperate with Humans, Computers Need to Integrate Evolutionarily Salient Variables

An important application of evolutionarily salient factors in game-theoretic modeling is direct interaction between humans and computers. For instance, in traditional Indian culture, friends and families arrange a marriage between a couple (Ghimire et al. 2006); in modern Western and Indian societies, this function is more frequently performed by interactive computer systems such as online dating websites and mobile apps. As computers become more involved in human social life, it may become more important to design more socio-cognitively aware computer systems. Game theory provides an important framework to study how human players interact with computers.

As PD models essential aspects of human cooperative behavior (Axelrod and Hamilton 1981), it is interesting to note that several PD studies report that humans use socio-evolutionary

behavioral cues in decision-making (e.g., see Eckel and Wilson 2003). In the PD framework (also in other games), fMRI studies report that humans use specific brain regions to anticipate opponent mental states (theory of mind) when making interactive social decisions but use the same regions to a lesser degree when interacting with computers (Rilling et al. 2004). This is likely to have grave consequences for automation and robotics as humans cooperate less with computer players, reciprocate less, and tend to perceive them as less open and agreeable, compared to other human players (Rilling et al. 2004; Sandoval et al. 2015).

Humans are wired to be social, and we seem to use several social-cognitive mechanisms such as theory of mind to navigate through life. When computers are implored to take over a function, they are usually economical and accurate, but currently they lack social-cognitive efficiency. For computers to be smarter, they need to account for evolved social-cognitive functions.

Conclusion

Humans exhibit peculiar patterns in prisoner's dilemma gameplay, which models social behavior. Several socio-evolutionary factors are likely explanations for these peculiarities. In order for computational systems to better interact with humans, it may be important to acknowledge and integrate evolutionarily salient mechanisms.

The process by which offspring are produced by their parents; in humans, reproduction is the combination of genetic material from two sexes, male and female, to produce offspring.

Introduction

While many of us may feel that we have a personal understanding of sex and reproduction, we rarely stop to consider how important the process of reproduction is to all life on earth. Reproduction is the method by which genetic material contained within an organism, whether it be within single-celled protozoa or in multicellular humans, is passed from one generation to the next. This movement of genetic material through generations is how evolution occurs; natural selection acts upon heritable differences between individuals and favors some genetic combinations over others. This makes how, when, where, and in many cases with whom you reproduce an especially significant question in evolutionary terms.

When we think about the concept of reproduction, we are usually thinking specifically about sexual reproduction. Sexual reproduction is ubiquitous, occurs in a large variety of taxa, and can be observed in single-celled organisms, plants, and animals. Sexual reproduction is the combination of genetic material from two different, distinct individuals that come together to create offspring that contain a full complement of that species’ DNA. Most organisms who sexually reproduce are diploid, meaning they carry two copies of

every chromosome in their somatic, or body, cells: one set they got from their mother and one set they got from their father. In humans, for example, all of our cells (excluding sperm and eggs) contain two sets of every chromosome; we have 23 pairs of chromosomes for a total of 46. For viable zygotes to be created, haploid cells (containing only one set of chromosomes from each parent) fuse together during fertilization to create a single diploid cell, which contains two complete sets of chromosomes (i.e., 23 pairs). These haploid sex cells are known as gametes, and in sexually reproducing species we define sexes based upon the size of an individual's gametes. The individuals in a species which produce larger, usually immobile gametes are referred to as females, and those who create smaller, motile gametes are referred to as males. For example, human females produce eggs that are many times larger than the sperm created by males.

Advantages of Sexual Reproduction

Sexual reproduction is ubiquitous in the natural world, which means that it must confer evolutionary advantages. One of the rather large benefits of sexual reproduction is a result of sharing genetic information between individuals, referred to as genetic recombination or simply recombination. Because each parent contributes a portion of the DNA needed to create a zygote, their offspring have a novel combination of genes that neither of their parents had. While this genetic shuffling may not seem very impressive on the surface, it opens the doors for many evolutionary benefits by creating new allele combinations and increasing genetic variety in populations (for a review of current hypotheses on the evolution of sex and genetic recombination, see Hartfield and Keightley 2012).

One benefit of sexual reproduction is the constant creation of genetic variety through recombination, which the Fisher-Muller hypothesis argues is better able to bring together favorable combinations of alleles than asexual reproduction (Hartfield and Keightley 2012). Sexual reproducers can combine beneficial genes into the same genomes through recombination, but for asexual reproducers to have two beneficial alleles

occur in the same line, each mutation has to arise independently in that line (which would take considerably more time and is also much less likely an occurrence). Sex can therefore create new combinations of genes and new phenotypes faster than asexual reproduction. Because recombination mixes genetic material, it can produce novel genetic combinations that may be more adapted to the environment than either of the parental genomes were.

Another benefit of sexual reproduction is that recombination purges deleterious mutations from a population. If one parent has many deleterious mutations and they mate with someone who does not, then it is possible due to recombination that their offspring will only carry some of the negative mutations they carried. Purging deleterious mutations from populations is important, as the higher a deleterious mutational load a population has, the more likely it is to go extinct (Hartfield and Keightley 2012).

Finally, sexual reproduction can also result in the complementation of negative recessive alleles (Hartfield and Keightley 2012). Complementation is the masking of a deleterious recessive allele by a dominant allele. For example, if a man who has cystic fibrosis, meaning he is homozygous recessive for the gene that causes the disease, has a child with a woman who is homozygous dominant for the allele which causes cystic fibrosis, then her functional copies of the gene will mask the dysfunctional copies in all of their children. None of their children will have cystic fibrosis because the dominant, functional allele compensates for the dysfunctional recessive allele.

Disadvantages of Sexual Reproduction

Although sexual reproduction appears to have many genetic and evolutionary benefits, it is not without cost. These costs become more apparent when we consider the case of asexual reproduction or parthenogenesis. In contrast to sexual reproduction, where two distinct gametes from two parents fuse together to create a new organism, asexual reproduction occurs in females whose offspring arise from an embryo where no fertilization occurs. In asexual species, male gametes are not necessary to produce viable offspring,

and therefore in asexual reproduction all of a female's offspring are genetically identical to her. In this system, females can avoid costs associated with sexual reproduction. Because asexual females do not need a partner to create offspring, they do not have to invest time and energy into acquiring and mating with partners, ventures that are quite dangerous and costly in some species as any time not spent devoted to maintenance of self and survival can greatly reduce life span.

In addition to skipping the costs of finding and acquiring mates, asexual females also enjoy avoiding what is referred to as the twofold cost of sex. The twofold cost of sex is based upon the theoretical ability of asexual populations to outreproduce sexual populations (Kodric-Brown and Brown 1987). Consider a population composed of a single asexual female and a single female-male pair, and suppose that each will contribute the same number of offspring to the next generation. This means that the asexual female will produce two offspring, and the male-female pair will produce two offspring (a male and female). In the next generation, there are now two asexual females who will produce four asexual daughters, but there is only one female-male pair, which will only produce two offspring (again). Because the female-male pair must share genetic information to produce offspring, the sexual population size remains the same in each generation, whereas the asexual population doubles in size each generation. In this simplified scenario, the twofold cost of sex should stipulate that asexual reproducers outcompete sexual reproducers in terms of sheer numbers.

The Evolution of Sexual Reproduction

There are clearly many costs associated with sexual reproduction, and considering the twofold cost of sex, it would seem that asexual populations are intrinsically able to outreproduce sexually reproducing populations (Kodric-Brown and Brown 1987). However, we frequently see the exact opposite occurs in nature, which suggests that the benefits of sexual reproduction in some way compensate for its costs.

One theory for the evolution and maintenance of sexual reproduction suggests that sexual

reproduction has been selected for so strongly because it provides better protection against rapidly evolving parasites when compared to asexual reproduction (Hamilton et al. 1990; Hartfield and Keightley 2012). This hypothesis is known as the Red Queen effect (also called the Red Queen hypothesis). It is named after a line in Lewis Carroll's *Through the Looking Glass* where the Red Queen says to Alice, "Now, here, you see, it takes all the running you can do, to keep in the same place" (Van Valen 1973). According to the Red Queen effect, species must very rapidly adapt and evolve to keep pace with parasites so that they are not driven to extinction; they must evolve or "run" very quickly only to stay in the same (extant) state. Parasites pose an evolutionary challenge to more long-lived species because they have a much smaller generation time compared to their hosts. This means that parasites can very rapidly evolve novel adaptations that allow them to better take advantage of their hosts within the host's lifetime. This is difficult for the hosts, whose longer generation time means they take longer to adapt reciprocal changes to fend off their parasites. It is this coevolutionary arms race between parasite and host, according to Hamilton et al. (1990) that has selected for and maintained sexual reproduction in populations despite its numerous costs. Thus, sexual reproduction is selected for over asexual reproduction because it generates more genetic variety in populations. Genetic variety is favored in the scenario between host and parasite because the more genetic variety the host population has, the harder it is for a parasite to infect all individuals.

Another major theory of the selection pressures that led to sexual reproduction is known as the mutational deterministic hypothesis, and it suggests that sexual reproduction evolved because it allows populations to purge deleterious mutations from a population (Kondrashov 1998; Hartfield and Keightley 2012). In all populations, sexual and asexual, mutations will occur due to inherent error rates in DNA replication and DNA maintenance and because of environmental factors that disturb these processes. An important aspect of new mutations is that they are much more likely to be deleterious than beneficial to organisms. In

asexual populations, if a deleterious mutation arises, all of the offspring from individuals carrying that mutation will also have it. In this scenario, deleterious mutations will continue to accumulate over generations, because the only way to purge negative mutations from asexual populations is for the organisms carrying them to stop reproducing or for another mutation to occur that reverses the effect of the initial deleterious mutation (an unlikely event). Because of this inability to purge deleterious mutations, these asexual populations will eventually accrue too many negative mutations and will most likely go extinct, a process referred to as Muller's ratchet (Kondrashov 1988). However, genetic recombination allows sexually reproducing populations to purge deleterious mutations at significant rates by mixing genetic material between parents to create offspring, which may help sexually reproducing species outcompete asexual reproducers (Hartfield and Keightley 2012).

Evolution of Two Biological Sexes

Although a few sexually reproducing species, such as slime molds, have evolved more than two distinct "mating types," most diploid, multicellular taxa that sexually reproduce have only two distinct biological sexes: male and female. This is theorized to be the result of differential selective pressures that gametes underwent very early on in the evolution of sex. These differential pressures on gametes started the cascade of evolution that has led to the differences we observe between males and females in all sexually reproducing species today (Kodric-Brown and Brown 1987).

To consider the pressures that early gametes may have experienced, we have to look back to when sexual reproduction was new to the evolutionary scene. Very early on in the evolution of sexual reproduction, the haploid gamete cells that organisms produced were isogamous, meaning that all gametes were the same size. Because isogamous gametes do not differ in terms of morphology, they are not classified as either male or female. Rather, the compatibility of gametes is determined by genes at specific mating-type regions in the genome. These isogamous

individuals are assigned mating types such as "+" and "−." Although isogamy was the ancestral condition of sexually reproducing species, most extant plant and animal species have subsequently evolved anisogamy (Matsuda and Abrams 1999). Anisogamy is the production of two morphologically distinct gametes and is the foundation of sexual dimorphism. Although males and females can vary greatly in terms of appearance and behavior in different species, the origin of that variance is rooted in differences in gamete size. In order to understand the evolutionary switch from isogamy to anisogamy, we need to consider how exactly gamete size is important for successful reproduction and what selective pressures may have led to the deviation away from similarly sized gametes between mating types.

Gamete size is important for successful reproduction because it is linked to the viability of future offspring; the larger the gametes that parents contribute to a zygote, the more cellular resources that zygote will have to successfully develop (Parker et al. 1972). Parker et al. (1972) contend that this relationship between gamete size and zygote viability is a continuum, wherein the more resources gametes contribute to a zygote, the more viable that zygote will be. However, parents cannot invest infinite amounts of energy in generating large gametes. Therefore, there is a fixed amount of resources that any parent can contribute to gamete production, and the more gametes they produce, the smaller the allotted resources will be. Because of this, there is a trade-off between how many gametes an organism can generate and how much those gametes can contribute to the viability of zygotes. Parker, Baker, and Smith used these parameters to generate a computer simulation to model isogamous populations. In this model, gamete sizes varied slightly between individuals in the parent population, gamete size was heritable, and gamete size responded to selection pressure. Gametes in this simulation were released and mated randomly, meaning they fused with the first gamete they encountered.

Interestingly, this model always generated populations that were eventually anisogamous. The authors concluded that this was because "proto-females" (i.e., individuals who produced

slightly larger gametes on average) had zygotes that survived well regardless of the size of the gametes they were fertilized with, which meant that producing larger than average gametes was a stable, successful strategy. On the other hand, “proto-males” (i.e., those who make more but smaller gametes) were more able to capture and fertilize those larger gametes produced by “proto-females” than intermediate gamete sizes because there were more of the smaller gametes. In other words, the smaller gametes were better able to parasitize the investment of larger gametes made by proto-females than intermediate gametes were and were more reproductively successful (Parker et al. 1972). This phenomenon is referred to as gamete competition, because as soon as a proto-male arises in a population, they can fertilize more gametes than gametes of an intermediate size and will outcompete the intermediate gametes (Parker et al. 1972). This places a selective pressure on other members of the population to either produce small competitive gametes or nutritive large gametes. This disruptive selection on gamete size has resulted in two distinct sexes among sexually reproducing species (Hartfield and Keightley 2012), although there can be more than one morphological type within a given sex (e.g., plainfin midshipman fish males have two types: sneaker and guarder males).

Sex Differences in Early Development

As time passed, differences in more than just gamete size began to evolve between males and females in anisogamous species. Today, in large, multicellular, anisogamous species females and males have evolved complex differences in gonads, internal genitalia, and external genitalia that impact how each biological sex develops, reproduces, and behaves. Although the development of the stereotypical set of human male and female gonads, internal genitalia, and external genitalia is considered below, there are many intermediates that arise between the male and female developmental pathways, and up to 2% of live births in the United States result in individuals who deviate from the stereotypical male or female reproductive tracts (MacLaughlin and

Donahoe 2004). This results in a spectrum of possible outcomes between the typical male and female phenotypes (for a review of intersex phenotypes, see MacLaughlin and Donahoe 2004).

All zygotes, regardless of chromosomal sex, begin as a bipotential embryo, meaning that they are capable of taking both the male and female developmental routes, a process that is known as sexual differentiation. At this point in development, zygotes have both Wolffian ducts (proto-male internal genitalia) and Müllerian ducts (proto-female internal genitalia; Hughes 2001). In humans, whether or not a zygote develops into a stereotypical male or female is determined by the presence of a gene known as the sex-determining region on the Y chromosome (SRY) gene, which is located on the Y chromosome (Hughes 2001). When a functional copy of this gene is present, it codes for a protein that activates other genes that begin the cascade of male-specific development. If this gene is absent or dysfunctional, then these male-specific genes are not expressed, and the female developmental pathway is undertaken.

The typical male pathway is initiated when the SRY gene induces the development of testes from bipotential gonad tissue (Wilhelm and Koopman 2006). The testes then secrete three key hormones: testosterone, anti-Müllerian hormone (AMH), and dihydrotestosterone (DHT). Testosterone is responsible for the development of internal genitalia, including the epididymis, seminal vesicle, and vas deferens, whereas AMH causes the proto-structures of the female-typical reproductive tract to regress (Wilhelm and Koopman 2006). DHT causes the development of male external genitalia. In contrast, the typical female developmental pathway is undertaken in the absence of a functional SRY gene. In this case, testis never begins to develop from the bipotential gonad tissue. This means that testosterone and AMH will not be produced, and in their absence the bipotential gonad tissue develops into ovaries, the Wolffian ducts regress, and the Müllerian ducts develop into the uterus, cervix, and part of the vagina (Wilson and Davies 2007).

Sex Differences in Later Development

Hormones play an integral part not only in the development of the reproductive tract but also in the psychosexual behavioral differentiation of males and females later in life. This phenomenon is referred to as the Organizational-Activational Hypothesis of hormones (Phoenix et al. 1959). It states that steroid hormones have two modes of action; first, during a critical window in the animal's early development, steroid hormones organize neural systems that are later responsible for generating sex-typical behavior. Then, upon sexual maturation, these same steroid hormones activate the neural pathways organized during development, which results in the organism performing sex-typical behavior when appropriately stimulated and in some cases developing secondary sex traits (such as facial hair in men or development of breasts in women).

The Organizational-Activational Hypothesis of hormones appears to be at play in the development as humans as well; prenatal exposure to testosterone and estradiol selectively prunes specific areas of the brain in a sexually dimorphic manner, which influences sex-typical behavior in later life (for a review of sexually dimorphic regions of the human brain, see Wilson and Davies 2007). For example, among those with congenital adrenal hyperplasia (CAH), where fetuses are exposed to abnormally high levels of testosterone due to a problem with an adrenal enzyme, female children will display more male-typical behaviors throughout their lives. As children, these females exhibit more rough-and-tumble play, less nurturing behavior, are more interested in male-typical toys and male playmates, as adults are more likely to enter a male-typical field, and are perhaps more likely to identify as bisexual or lesbian as adults (Hines et al. 2004). This suggests that early exposure to high levels of testosterone during their gestation may have masculinized some of their female sex-typical neural pathways.

Another line of evidence that early exposure to hormones can alter sex-typical behavior later in life comes from individuals with complete androgen insensitivity syndrome (CAIS). When CAIS

occurs in genetic males who have a mutated copy of the androgen receptor gene which makes them completely unresponsive to the androgens (testosterone and DHT) that their testes produce (Hughes et al. 2012), these males develop as female. Specifically, because their bodies cannot react to androgens during development, their phenotypic development follows the female-typical pathway, and although they lack a uterus and have internal testes, they also exhibit female-typical, sexually dimorphic behavior and have a female gender identity (Wilson and Davies 2007). This suggests that the absence of the effect of androgens early in development not only caused the development of a physical female phenotype, but it also prevented male-typical behavioral pathways from developing.

Ultimate Explanations for Sexual Dimorphism in Humans

Men and women clearly differ when it comes to their physiology and, in some cases, their psychology (Wilson and Davies 2007; Collaer and Hines 1995). The proximate cause of these psychological differences is due in part to the differential developmental pathways that typical males and females undergo during development and the hormones that influence their behavior and secondary development later in life. Why then, ultimately, do men and women seek different qualities in mates? Why are they different behaviorally and psychologically in some romantic and sexual aspects, but not in others? Two theories that seek to explain the evolutionary pressures that differentially shaped men and women's development and behavior in relation to reproduction are (1) Buss and Schmitt's (1993) sexual strategies theory (SST) and (2) Gangestad and Simpson's (2000) strategic pluralism theory (SPT).

Sexual Strategies Theory

The SST posits that throughout our evolutionary history, humans have sought specific mates to solve specific adaptive problems. The choices men and women made were contingent upon the context and the temporal nature of the relationship (i.e., short- vs. long-term relationships). In some

cases, because men and women faced different adaptive problems, they have evolved different strategies when it comes to finding and pursuing relationships with the opposite sex.

A major asymmetry between the sexes that has influenced the evolution of sexual differences is the amount of parental investment that each sex must contribute to offspring (Trivers 1972). If both sexes were to invest the minimal amount of time and energy possible into an offspring, the male would spend only the amount of time and energy it took to generate sperm and fertilize a woman's egg. The female, however, must generate a much larger gamete, gestate the fertilized egg for 9–10 months, and then give birth. This difference in minimal investment sets up a dichotomy in terms of the most beneficial reproductive strategy for men and women. According to Buss and Schmitt, although both sexes benefit from long-term relationships wherein each parent contributes substantially to the success of their offspring, men benefit more from having conditional short-term engagements than women do and will therefore seek more short-term relationships, on average, than women. It is this discrepancy in what optimizes each sex's reproductive success that has led to the evolution of different reproductive behavior in men and women.

When it comes to short-term relationships, men, who are limited by the number of eggs they can gain access to and fertilize, are most benefited by factors such as finding more partners and identifying partners that are potentially fertile. Buss and Schmitt (1993) found that men do appear to desire more short-term relationships than women and express a greater desire for more partners in the immediate and distant future than women express. Additionally, there is evidence that men may be able to detect the fertility status of women based off of subtle changes in their physiology, such as in the pitch of their voice or in body odor, which change in response to where women are during their menstrual cycle (reviewed in Haselton and Gildersleeve 2011). On the other hand, women's short-term concerns deal more with gaining resources, such as increased social status, because they are not restricted by the number of partners they can

accrue. Li and Kenrick (2006) found that when women were tasked with spending a budget of "mate dollars" to buy characteristics to create an ideal short-term mate, they spent a significantly higher amount of their restricted budget on a partner with higher social status and resources than men did when given the same task and budget.

In terms of longer relationships, both men and women must solve the problem of finding mates with good parenting skills and a willingness to commit to long-term partnerships. Men, however, must also be concerned with paternity certainty and attaining mates who have high reproductive value, whereas women are constrained by attaining partners who are able and willing to invest time and resources into their offspring in the long-term. It appears as though men place value on traits in partners such as faithfulness and sexual loyalty and also have psychological adaptations such as jealousy for detecting sexual infidelity threat, which may help solve the problem of paternity certainty (Buss and Schmitt 1993). Additionally, it appears that cross-culturally men prefer long-term partners who are younger than they are (about 2–3 years younger), whereas women prefer men who are older than they are (3.5 years older; Buss 1989). This may be a psychological adaptation for both sexes; preference for younger women may help men find highly fertile partners, and preference for older men may help women find men who have more resources to invest in them and their potential offspring.

Strategic Pluralism Theory

It is important to note that there is no one "best" strategy that all men or all women adopt all of the time. Although the SST does propose that both men and women have evolved mixed strategies wherein both sexes can and do choose to pursue both short- and long-term relationships, the SPT proposed by Gangestad and Simpson (2000) proposes that the strategy either sex pursues is dependent on cues from the environment. Although differences in minimal parental investment still influence the mating choices men and women make, SPT posits that there is also considerable

intrasexual variation in strategy choice. What strategy an individual adopts is contingent upon environmental cues that allow them to make cost-benefit decisions when it comes to mating strategy. These cues include many conditional extrinsic factors, such as the availability of mates, number of competitors, and quantity of available resources, in addition to intrinsic factors, such as how attractive one is and how able they are to obtain short-term mating partners (Gangestad and Simpson 2000).

Interestingly, these conditional factors may better explain women's short-term mating strategies. SPT contends that, in addition to extracting resources from partners, women also take into account access to good genes when making short-term mating decisions and may have evolved to seek good genes for their offspring from short-term relationships. In the same study using "mate dollars" described above, the authors found that both sexes highly prioritized attractiveness for short-term partners. However, Li and Kenrick (2006) note that what constitutes physical attractiveness differs between the two sexes, whereas men prefer estrogen-linked traits, such as breast symmetry, which are associated with fertility in women, and women prefer testosterone-linked traits like facial masculinity (at least, for a short-term relationship), which may be markers of good, immunocompetent genes (see, e.g., Pillsworth and Haselton 2006). Women, therefore, also prioritize attractiveness for short-term partners (but not long-term partners), which may indicate that access to good genes is a contributing factor in women's choices to pursue short-term partnerships (Pillsworth and Haselton 2006).

Pair-Bonding as an Adaptation for Reproduction

Another key component of the reproductive strategies of both men and women has been the evolution of pair-bonding. Pair-bonding is the long-term formation of a very close social and sexual bond to another human being that exists outside of the typical relationship shared with an acquaintance (Quinlan 2008). Not only is the formation and maintenance of pair-bonds facilitated by

complex neurological and hormonal networks in our bodies and brains (Young and Wang 2004), pair-bonding also occupies a large portion of the collective mental energy of our species. Pair-bonding and the experience of being in love have inspired countless creations of music, poetry, literature, and art among other manifestations, all of which are an integral part of human culture. The formation of long-term social partnerships, be it inside or outside of a marriage, appears to be culturally universal as does romantic love, both of which have significant implications for human reproduction (Jankowiak and Fischer 1992).

Two explanations for the evolution of pair-bonding in humans consider selection pressures for parental investment and male-male competition. Because newborns require so much nourishment and rearing to ensure survivorship, it is in the father's best interest to sacrifice some potential mating opportunities to help provision their offspring to increase its likelihood of survival (Trivers 1972; Quinlan 2008). Pair-bonding may therefore have evolved as a mechanism to increase biparental and cooperative care for offspring from both parents. On the other hand, it is also possible that pair-bonding could have evolved as a consequence of male-male mating competition. Because of the operational sex ratio in humans, at any time there are many fewer fertile, ovulating women than there are men who can fertilize their eggs. This means that males must compete with one another to gain access to females. From this perspective, pair-bonding may have evolved as a mechanism to prevent other males from gaining access to a pair-bonded female by facilitating mate guarding by her partner (Quinlan 2008).

Philosophy and Reproduction

As such an integral part of our existence, the act of reproduction itself has garnered its fair share of intrigue and evaluation from philosophical minds. Is it always the most ethically and morally correct decision to reproduce? When is it appropriate to reproduce and when to refrain from reproducing? Two viewpoints regarding reproduction that have been articulated in part since ancient times are natalism and antinatalism. Natalism is a belief

that human reproduction should be encouraged and encompasses a range of viewpoints, such as the idea that human reproduction is of the ultimate importance and philosophical considerations of the value of bringing another human into the world. On the other hand, antinatalism views reproduction in a negative light and considers the suffering associated with being brought into existence, the impact of humans on other species on our planet, and the impact of humans on our environment, among other factors arguing that birth is unfavorable.

Two prominent pro-natalism thinkers are David Wasserman and Rivka Weinberg. When it comes to whether or not it is morally permissible to have children, Wasserman argues that in many cases it is permissible but that this is only the case when the rights of the future child to live a life with a minimal standard of well-being are considered and met (Benatar and Wasserman 2015). Although this argument is permissive of reproduction, it also heavily rests on the moral stature of the parents, as Wasserman argues that for reproduction to be permissible parents must bring children into the world with the intent of giving those children lives worth living (Benatar and Wasserman 2015). Rivka Weinberg proposes that giving birth is an imposition of risk on an unborn child. In this light, it is only morally permissible to procreate when the risk imposed on a child is a risk you would have accepted as a condition of your own birth and that parental motivation to have children should be driven by the want and intention to love and care for those children (Weinberg 2015).

On the other hand, a prominent antinatalist, David Benatar, proposes that to bring someone into the world always does that person irreparable harm (Benatar and Wasserman 2015). His argument is based off of two lines of reasoning: (1) that by having a child you cause all of the good and bad that that child will experience during their lifetime and (2) that even when one accounts for all of the good and bad in a life, the bad far outweighs the good. When one considers the case of nonexistence, the absence of pain is good, and the

absence of pleasure is not bad, because there is no one there to deprive pleasure of (Benatar and Wasserman 2015). From this perspective, it is better to never have existed, because there is nothing bad about not having come into existence, whereas coming into existence necessitates that you experience painful things.

Is Modern Life Changing Reproduction?

Modern medical technologies such as in vitro fertilization have emerged in the last few decades, which now allow couples to conceive when previously they would have been unable to. These technologies, collectively known as assisted reproduction technology (ART), are a hope for the estimated 80 million individual worldwide who experience infertility or subfertility (Vayena et al. 2002). Although ART has been a boon to many, it has been a concern to some because ART may be bypassing some important biological filters that otherwise do not allow for two individuals to conceive (Niemitz and Feinberg 2004). Although developmental pathways have evolved to withstand or buffer a certain amount of changes in genotype and environment, it is possible that ART in some cases may be causing that buffer to break down. For example, ART might be interfering with embryo imprinting and epigenetic maintenance of fetal gene expression, which both may lead to problems with development (Niemitz and Feinberg 2004).

Another aspect of modern life that is influencing how individuals choose to reproduce is concerns with overpopulation. An important example of this is China's one-child family policy, which was enacted in 1979 amidst concerns that a booming population would cause a large sacrifice in living standards (Hesketh et al. 2005). This policy was meant to create a shift toward small-family culture and has been more strongly enforced in urban, highly populated areas than in rural sectors. However, an unintended consequence of this policy has been a change in the sex ratio in China toward male children, as traditionally boys are preferred to girls. Preimplantation genetic diagnosis (PGD) and early fetal sexing in combination

with sex-selective abortions have decreased the number of female children born in China. This, in combination with poor medical treatment of female children resulting in a higher female mortality rate, has significantly altered the sex ratio in China. This shift in the sex ratio has been associated with a doubling of crime rates, an increase in demands for sex workers, and an increase in the transmission of HIV (Tucker et al. 2005). From an evolutionary perspective, artificially altering the operational sex ratio and the availability of mates may alter the intensity of competition for mates, changing human mating dynamics, behavior, and preferences.

Conclusions

How, when, and with whom we choose to mate are a complicated process that has been influenced by many factors: by the earliest evolution of sex, how our brains and bodies develop pre- and post-natally and into later life, what evolutionary pressures have shaped our species over time, the culture we are surrounded by, and the intrinsic values and characteristics that are unique to each of us. Although humans exist in a vast range of geographical locations and our cultures vary across them, the mating preferences we have evolved over our species' history are still at play, and how these preferences interact with modern technology and culture will have significant impacts on the evolutionary future of our species.

Definition

Reproduction, suicide, and euthanasia are existence-related moral phenomena with the mutual component of decision-making regarding life and death.

Introduction

Natural selection will never produce in a being any structure more injurious than beneficial to that being, for natural selection acts solely by and for the good of each. No organ will be formed for the purpose of causing pain or for doing an injury to its possessor.

Charles Darwin

Does life stink? There is, obviously, no simple answer to this philosophical question. David Benatar (1997, 2006) argues that life stinks, and even if it does not stink so badly, there is a good chance that it will begin to do so. Existence may be painful and frustrating; however, nonexistence cannot be painful or frustrating. Back to the first fundamental question of this entry, nonexistence is completely “odor-free.” Benatar (2016) further argues that since it is better never to exist, one is harmed by being brought into existence. This author concludes that procreation is “always” wrong and morally problematic (for a discussion see Weinberg 2012). This philosophical idea is not new in philosophical writings and has inspired many noble writers and thinkers (e.g., Sadegh Hedayat; see Fadaei 2009).

The line between existence and nonexistence and its moral factors have been the center of heated debates over the centuries. Psychologically speaking, morality is tightly associated with *decision-making*. There are three important, existence-related phenomena that are tied to the concept of decision-making: reproduction, suicide, and euthanasia. In the former, two persons usually make a conscious decision to produce offspring. The other two concepts entail deliberately putting an end to one's life. These three phenomena and their related factors have been largely discussed in philosophical, sociological, psychological, and bioethical texts.

In evolutionary psychology, *survival* and *reproduction* are probably among the most widely mentioned keywords. Both keywords are associated with the "line between existence and nonexistence." Evolutionary psychologists argue that humans, over deep evolutionary history, have developed psychological mechanisms in order to reproduce and guard their offspring at least until they become sexually mature to be able to reproduce. The evolutionary psychology of suicide and euthanasia is, however, more puzzling because individuals consciously hinder survival. While evolutionary psychological understanding of suicide and euthanasia seems complicated or puzzling, evolutionary psychologists have adequately addressed these issues. In what follows, a short description is given for each behavior (i.e., reproduction, suicide, and euthanasia). Of note, there are other existence-related phenomena which are greatly influenced by moral decisions (e.g., abortion) that are discussed at length in other entries.

Reproduction

As an empirical science, evolutionary psychology has successfully described, explained, and predicted human reproductive behavior; however, maybe it has remained neutral on "badness" or "goodness" of reproduction. Existence may be either pleasing or frustrating, and much of this attribution is formed through the quality of parental care which is an evolved psychological

mechanism. Consistently, research suggests that insecure attachment is strongly associated with depressive symptoms (Burnette et al. 2009). A considerable proportion of the literature in evolutionary psychology has focused on mating whose primary purpose is successful reproduction. In different cultures, and depending on environmental features, people deploy various reproductive strategies in mating context, and there are culture-specific values and religious teachings that promote reproduction.

From an evolutionary viewpoint, offspring are a sort of vehicle for their parents (Buss 2008). Parents' genes may get transported to succeeding generations through successful reproduction. Without children, an individual's genes may perish forever, and again, to a typical evolutionary psychological scientist, this is neither "bad" nor "good." Considering the paramount importance of offspring as genetic vehicles, it stands to reason to expect that natural selection would particularly favor powerful mechanisms in parents (e.g., parental care) to ensure the survival and reproductive success of their offspring. Of course, without the success of offspring in reproduction, all the effort that was previously invested in mating would be reproductively meaningless. By investing in offspring, parents miss resources that could be potentially devoted to themselves. Parents who protect their young children risk their own survival. In some cases, some parents become wounded or even die while protecting offspring from predators. Given the costs associated with parental care, it is reasonable to expect that reproductive benefits of parental care are large enough to outweigh the abovementioned costs.

Suicide

To someone who commits suicide, existence truly stinks! Life is a frustrating and "bad" experience for such persons. In fact, there is a well-developed research literature on the relationship between depression and suicide. There are a number of philosophers and writers who actually committed suicide after writing brilliant literary works on life

and death (Fadai 2009). Existing evidence shows that suicide has occurred throughout history and across the world. Something that is not bound to a specific place or era and happens in high rates should be fundamentally traced back to human nature. Suicide is, as worded by David Buss (2008), a genuine evolutionary mystery. At first sight, it seems so contrary to anything that evolution would favor. Evolutionary theory suggests that differential reproduction is the engine of the evolutionary process and survival is obviously necessary for reproduction. So how can evolutionary theory account for suicidal ideation and behavior?

An evolutionary psychological theory of suicide has been postulated by de Catanzaro (1991, 1995). According to this theory, suicide would be most likely to occur when an individual has a considerably reduced ability to contribute to his or her own inclusive fitness. This reduced capacity consists of indicators such as poor health, poor prospects for heterosexual mating, chronic illnesses, and perceptions of being a burden on one's genetic kin. Importantly, all these conditions are subjective and are not necessarily accurate in reality. Under these conditions, it is at least plausible that the replication of an individual's genes would have a better chance without his or her physical presence. For example, if an individual perceives that he is being a burden to his family, then kin's successful reproduction, and consequently the person's own fitness, might suffer as a result of his physical, fruitless presence. To empirically test this evolutionary theory of suicide, de Catanzaro (1995) collected self-reports of suicidal ideation (i.e., thoughts about how to kill oneself, which can range from a detailed plan to a fleeting consideration and does not include the final act of killing oneself) and the fitness-related variables (i.e., perceived burdensome to family, perceived significance of contribution to society and family, success with heterosexual mating, homosexuality, sexual activity, financial welfare, number of friends, social status and approbation, and physical health condition). Findings of de Catanzaro (1995) supported the outlined theory. The evolved suicide adaptation

hypothesis has also successfully explained sex differences in suicidal ideation (Buss 2008).

In conclusion, suicidal ideation and behavior have been, to some extent, explained by evolutionary theory. Yet, more research is warranted to explore evolutionary adaptations behind suicidal ideation and behavior. There are other sorts of suicidal behavior and suicide-related analyses that were not addressed in this entry (e.g., bargaining suicidal behavior, parasite manipulation; for a review of different evolutionary hypotheses regarding suicidal behavior, see Aubin et al. 2013; for a review of evolutionary psychology of suicide terrorism, see Liddle et al. 2011).

Euthanasia

Broadly, euthanasia is succinctly defined as the practice of intentionally ending a life in order to relieve pain or suffering. Euthanasia, meaning "good" or painless death (from the Greek *eu*, "good," and *thanatos*, "death"), was used in the last decade of the twentieth century to mean a death that is perpetrated or accelerated with the help of medicine. There are at least two classifications for euthanasia, one on the *decision-making* process and the other on the form of death. The first classification suggests that three types of euthanasia can be practiced: voluntary, involuntary, and non-voluntary. *Voluntary euthanasia* is that which is requested or agreed to by the subject. *Involuntary euthanasia* is practiced when the agreement of the subject could be obtained, but is not. *Non-voluntary euthanasia* is that in which the agreement of the subject cannot be obtained because of his or her physical or mental state. The second classification suggests that euthanasia could be active or passive. The former is where death is produced deliberately and actively, while the latter applies where death is purposely produced by withholding or withdrawing of the medical means of nutrition or the treatment of the subject's condition. Physicians assist suicide when they intentionally help a person commit suicide by providing lethal drugs for self-administration.

Voluntary euthanasia and physician-assisted suicide are quite similar to regular suicide in terms of decision-making, that is, one consciously decides to end his or her own life. However, the distinction between voluntary euthanasia and suicide rests upon the presence or absence of an incurable and progressive disease that is inevitably drawing the patient toward death. Therefore, voluntary euthanasia and physician-assisted suicide can be adequately explained by de Catanzaro's (1995) evolutionary model of suicide. Involuntary and non-voluntary euthanasia may be explained by the notion that ending patient's life could enable the family members and genetic relatives to redirect their resources (e.g., time, energy, and money) from keeping the patient alive to other domains. Generally, treatment of end-stage patients is very costly for the family or the society and limits family's ability to invest in other potentially reproductive domains.

Conclusion

Reproduction, suicide, and euthanasia are important concepts with the mutual factor of decision-making with regard to life and death. Reproduction is a crucial behavior in human evolution as offspring are the vehicles through which parental genes get transported into future generations. Suicide has been referred to as a "puzzle" because it seems paradoxical to every adaptation in evolutionary history for survival. However, evolutionary psychologists have documented explanatory theories and hypotheses regarding different types of suicide. Euthanasia is also a moral dilemma which has been investigated in different disciplines from bioethics to personality psychology. Evolutionary foundations of different types of euthanasia were also discussed. In sum, evolutionary psychology may inform different fields of study regarding the mentioned phenomena that are closely associated with existence and nonexistence. Of note, evolutionary psychology, as an empirical science, is more involved in explaining *functions* of each behavior rather than judging it as either "good" or "bad."

Reproductive Frequency

Gordon G. Gallup¹ and Jennifer A. Stolz²

¹State University of New York at Albany, Albany, NY, USA

²Department of Psychology, University of Waterloo, Waterloo, ON, Canada

Definition

High frequency sex is an adaptation to the loss of cues needed to synchronize insemination with ovulation, and it promotes conception in species with low reproductive rates. Moreover, high frequency sex promotes semen tolerance and semen sampling. It also serves as an algorithm for paternal commitment, functions as an anti-cuckoldry strategy, and reduces the risk of prostate cancer.

Introduction

Some species engage in high frequency sex (*iteroparous* species); others only have sex once in a lifetime (*semelparous* species), if they are lucky. Species differences in reproductive frequency evolved to promote their *replacement value*. For sexually reproducing species where each individual has two parents, the replacement value of two offspring for the parents is the

equilibrium point for that population. An average replacement value that exceeds 2 means the size of the population will increase, while a value of less than 2 will cause the population to shrink and if it remains in effect long enough eventually the species will go extinct.

Variation in one of two evolved strategies can be used to promote replacement values of 2 or more. Species that rely on *r-selection* produce large numbers of offspring but invest little time or effort in any of them. In salmon spawn, for example, the female releases thousands of eggs. As a result, salmon can produce hundreds of fry on a single reproductive occasion, and spawning in Pacific salmon triggers mechanisms that lead to the death of the parents within a matter of days. As a result, when the baby salmon hatch they will have to fend for themselves and many will perish, but the production of a lot of baby fish increases the odds that at least two will survive to complete the cycle and spawn thereby numerically replacing their parents in the next generation.

Species that are *K-selected* produce a small number of offspring but in terms of time and resources invest heavily in each of their progeny. Humans anchor the reproductive strategy at the end of this continuum. Women typically only produce one child at a time and they provision, protect, and care for their offspring for as long as several decades. Reproduction for women puts their capacity to be re-impregnated on hold for 3 or more years. That is because pregnancy lasts for nine months and breastfeeding (which until recently was the only option) typically lasted in the environment of evolutionary adaptiveness for 2–3 years. Breastfeeding produces hormonal changes which serve to suppress or inhibit ovulation. This is referred to as *lactational anovulation*. Because the biological costs of pregnancy and lactation are so high, lactational anovulation evolved as a birth spacing mechanism to afford the uterus a chance to recover from the previous pregnancy before being impregnated again (Gallup and Hobbs 2011; Gallup et al. 2016). As a consequence, humans have an unusually low reproductive rate.

Another factor that may contribute to the frequency of sex involves timing. Because humans

no longer engage in prominent patterns of seasonal breeding and human females no longer produce salient ovulatory cues, patterns of high frequency sex and continuous breeding represent an adaptation to the loss of ovulatory cues (see Gallup and Stolz [in press](#), this volume).

Orgasm and High Frequency Sex

Other things being equal, you would expect the frequency of sex to be proportional to the pleasure that the participants derive from sex. Consistent with this view, orgasm frequency in female college students is highly correlated ($r=.82$) with orgasm intensity (Gallup et al. 2014). The capacity to experience an orgasm is a byproduct of neurological mechanisms that evolved to promote the reoccurrence of the reproductive act in species with low reproductive rates (Gallup et al. [under review](#)).

There is also reason to believe that high frequency sex may be used by some men to keep their female partner sexually satiated and thereby less likely to engage in sex with other men (Kaighobadi and Shackelford 2008). Thus, an insistence on high frequency sex may also function as an evolved anti-cuckoldry strategy (for a review see Gallup and Burch [in press](#)). High frequency sex also promotes semen tolerance and semen familiarity which serves to facilitate healthier pregnancies by reducing the risk of preeclampsia and spontaneous abortion (Davis and Gallup 2006). Indeed, some people have theorized that being inseminated by a range of prospective mates during courtship may enable women to make more biologically informed mate choices (Gallup and Reynolds 2014).

Finally, there is evidence that high frequency sex and ejaculation also reduce the risk of prostate cancer (Leitzmann et al. 2004).

Reproductive Strategies

Definition

A cluster of interrelated physical, psychological, and behavioral characteristics that reflect selective allocation of time and energy toward propagation. The term “strategy” does not imply conscious decisions on the part of the organism, but rather refers to the nonrandomly organized set of characteristics that make up a reproductive phenotype.

Introduction

Reproductive strategy is an often used term in the evolutionary psychology literature that is rarely formally defined. It is generally used to refer to aspects of a reproductive phenotype along “fast” and “slow” dimensions, such as slow versus fast reproductive traits and behaviors or short-term versus long-term mating strategies. These fast and slow reproductive strategies are typified by quantitatively different clusters of characteristics that serve different reproductive goals. A fast strategy favors earlier reproduction, multiple offspring, and low parental investment. In contrast, a slow strategy favors delayed reproduction, fewer offspring, and high parental investment. Reproductive strategies are not necessarily fixed for either a population or an individual. In fact, humans often use a mixed strategy that includes aspects of both fast and slow strategies. Sex differences in reproductive strategies are well documented and are related to variability in attachment security.

Development of Reproductive Strategies

Early thinking on the development of reproductive strategies in humans can be found in Draper and Harpending (1982) and subsequently Belsky et al. (1991), both of which are based in life history models of development. Generally speaking, psychosocial acceleration theory (also sometimes termed the BSD model; Belsky et al., 1991) posits that early developmental

experiences, in particular parent–child relations and processes, serve to entrain developmental trajectories toward phenotypes that will ultimately match adult reproductive ecologies. Relevant parent–child relations/processes include harsh parenting, parental rejection, inconsistent parenting, and/or unpredictability and are hypothesized to foster a general reproductive strategy characterized by early pubertal timing, earlier onset of sex and reproduction, less stable pair-bonds, more offspring, and lower investment in each. In contrast, parent–child relations/processes that are more warm, supportive, and consistent should foster a reproductive strategy characterized by later pubertal development, later age at first sex and reproduction, more stable pair-bonds, and greater investment in fewer offspring.

Sex Differences in Reproductive Strategies

Sex differences in reproductive strategies can be traced back to anisogamy in humans. Anisogamy refers to sexual reproduction that involves the fusion gametes of unequal size. In humans, the larger gamete is female (ovum) while the smaller gamete is male (sperm). The larger gamete is more energetically costly to produce and the sex with the larger gamete must invest more in its production and, consequently, will produce fewer. The sex that produces the smaller gamete invest less in their production and can thereby produce more and increase their reproductive success via multiple fertilizations. Evolutionary processes, such as disruptive or diversifying selection, can select for the tails of the gamete-size distribution and lead to a population divided by two distinct sexes. Reproductive strategies and sex differences in reproductive strategies derive from these gamete-size differences and evolutionary processes. Because of the larger investment needed for larger gametes, females should be selected (on average) to be more discriminating when choosing reproductive partners. Males, however, should be less discriminating due to the inexpensiveness of the gamete and their ability to produce many. One

consequence of lower discretion is higher male conspecific competition for reproductive opportunities.

Extending from anisogamy are differing environmental influences on reproductive strategies. Women are relatively constrained by the resources they can extract from the environment, reproductive partners, and relatives to produce and rear offspring. As a result, women should be more attuned to the local ecology and cues to the availability of resources. One such source of information is parenting experiences, as described in the BSD model. Thus, girls' reproductive strategies should be relatively more influenced by these experiences compared to boys. Similarly, because men's reproductive success is constrained by their ability to attract and retain mates, male reproductive strategies should be more greatly influenced by their relative standing among other male competitors (James et al., 2012).

Additional research links sex differences in attachment to differences in reproductive strategies. For example, Del Giudice (2009) suggests sex differences in attachment security emerge during middle childhood as part of a sex specific reorganization of the attachment system. Differences in attachment patterns and reorganization in middle childhood consequently result in different reproductive strategies in adulthood. Insecurely attached boys and girls develop different attachment patterns during middle childhood that reflect sex-specific characteristics needed to enact reproductive strategies geared toward faster reproduction. Boys tend to develop an avoidant attachment style, which is characterized by higher aggression, self-reliance, and self-esteem, which are potentially beneficial in the context of high male conspecific competition. Girls, on the other hand, tend to develop ambivalent attachment styles that facilitate faster reproductive strategies (avoidant attachment) that may include tactics aimed to elicit investment from partners (anxious attachment). Securely attached individuals of either sex are expected to develop reproductive strategies based on more stable pair bonds, fewer offspring, and higher parental investment (i.e., slow reproductive strategy).

Conclusion

Reproductive strategies are defined by clusters of characteristics that are nonrandomly organized and that facilitate optimal propagation. On one end, a reproductive strategy is characterized by fast/short-term reproductive features that include earlier pubertal timing, earlier reproduction, multiple offspring, and low parental investment. On the other end, a reproductive strategy that can be characterized by slow/long-term reproductive features includes later pubertal timing, delayed reproduction, fewer offspring, and high parental investment. Research and theory point to early developmental experiences as a key factor for regulating reproductive strategies, although this may be more so for girls than for boys. Boys' reproductive strategies may be more influenced by competition among peers. Reproductive strategies are thought to be mediated by attachment security, which may explain some additional sex differences (Sung et al., 2016).

Reproductive Suppression and Sexual Conflict During Mating

Rebecca L. Burch
State University of New York at Oswego,
Oswego, NY, USA

Definition

Competition takes place during coitus between males and females to control fertilization and reproduction. Research indicates that males may use seminal fluid chemistry to influence female

reproduction in response to females concealing their ovulation.

Introduction

Female mammals and other species are normally sexually receptive around ovulation, and the ovulatory period is advertised to males by distinct visual, behavioral, or pheromonal signals. Most species possess slight or overt ovulation, showing vulval swelling or reddening, while others have marked sexual swellings including perineal skin (Sillen Tullberg and Moller 1993). The contrasting pattern of damped or concealed ovulatory signals accompanied by sexual receptivity outside of the ovulatory period is frequently referred to as concealed ovulation (Andelman 1987).

There is consensus in the literature that mating system and signs of ovulation are strongly correlated, if not involved in a causal relationship (Alexander and Noonan 1979). Sillen Tullberg and Moller in 1993 completed a phylogenetic analysis using two behavioral characters: the presence of ovulatory signals and type of mating system (monogamous, multi-male, or uni-male). They concluded that in the majority of instances, when ovulatory signs have been lost, it has been in a nonmonogamous context. They go on to state that of the extant monogamous taxa, none possess sexual swellings and most have no visual ovulatory signs, which would indicate a connection between monogamy and lack of ovulatory signals. The absence of signs is much more tightly coupled with monogamy than with any other mating system and the absence of ovulatory signs could be an important, though not necessary prerequisite for the evolution of monogamy if concealed ovulation evolved first. The most cited hypothesis regarding the evolution and adaptivity of concealed ovulation was put forth by Alexander and Noonan (1979). This stated that females concealed ovulation as a strategy to obtain male aid for females and children.

Given this information, it is not extraordinary to suspect that concealed ovulation has created a selection pressure in human males to either better

detect ovulation or develop counter strategies. Research indicates that one possible counter strategy to concealed ovulation is the chemical composition of human semen (Burch and Gallup 2006).

Many induced ovulation species do not show ovulatory signals. Research in induced/spontaneously ovulating species shows that not only is it the seminal fluid that induces ovulation but also it is a factor that is a potent stimulator of luteinizing hormone (Adams and Ratto 2013). These “ovulation induction factors” (bioactive prohormone forms) are absorbed through the female reproductive tissue into the bloodstream and have been shown in rats, Bactrian camels, alpacas, koalas, llamas, cows, mice, and rabbits.

Human seminal plasma contains estrone, estradiol, follicle stimulating hormone, luteinizing hormone (Ney 1986), and luteinizing hormone releasing hormone. Of these, luteinizing hormone releasing hormone is the most appropriate as an OIF candidate, acting in physiologically similar ways to the OIFs listed above. However, human males also have five times more LH in their semen than circulating blood levels (Ney 1986). OIFs may not be needed when luteinizing hormone is in such high levels. Induced ovulation in humans could be due to luteinizing hormone, luteinizing hormone releasing hormone, or another OIF.

Cutler et al. (1979) first investigated this when seven of the eight women studied who experienced extreme cycle lengths also had sporadic sexual behavior. These authors in 1980 showed that there were no aberrant short menstrual cycles and relatively fewer cycles that lasted over 33 days among the regular sexually active women. Veith et al. (1983) investigated the effect of exposure to males (sexually or sleeping) to ovulation. Ninety-two percent of the women who spent two or more nights with a male ovulated, as compared to only 56% of the women who only spent one night or less with a male. However, no relationship was found between sex and ovulation. It was suggested that it was not the number of sexual encounters, but the consistency that had an effect on ovulation.

In 1985, Cutler et al. found that women who maintained a weekly coital frequency had no incidence of short cycles and no very long cycles. Women who reported regular weekly sex with men had a greater incidence of fertile menstrual cycles. Finally, 1991, Burleson et al. studied the effect of heterosexual activity on menstrual cycle variability. Celibate women had more variable cycles than regular women, even when gynecological maturity was controlled for. This is similar to the Whitten effect in rodents where females isolated from males display irregular cycles.

It is important to note that all studies found that sex had to be consistent to have an effect on the menstrual cycle. This is very interesting in light of the effect of concealed ovulation on the human mating system. It is possible that not only did concealed ovulation demand greater male investment but also the female reproductive system functions better with consistent male physiological “investment.” For example, preeclampsia studies show a cumulative benefit of semen exposure over time; limited sex or condom use is linked with increased risk (Klonoff-Cohen et al. 1989), and the effect is partner-specific (Dekker et al. 1998).

Conclusion

In summary, males and females throughout human history have created selection pressures upon each other, as they competed to meet their reproductive goals. For women, ovulation became concealed, which resulted in greater paternal investment and more positive child outcomes. For men, semen chemistry evolved to better synchronize insemination with ovulation, increasing (among other things) fertilization rates.

Definition

For conception to occur, both temporal and spatial proximity are required for the release of male and female gametes.

Introduction

Sex alone will not suffice when it comes to reproduction. Among most sexually reproducing species, insemination (the deposit of male gametes) must be proximate to ovulation in both time and space in order for conception to occur. Because sperm viability is short-lived in humans (Gallup et al. 2009), insemination and ovulation must be tightly coupled in time; certainly no more than ± 24 h and probably closer to ± 12 h. While sperm may be capable of staying alive in the female reproductive tract for longer periods of time, once activation occurs with the introduction of sperm into the vagina, they rapidly lose the ability to achieve capacitation (a sudden increase in vigorous activity when sperm encounter an egg in the fallopian tubes that is needed to penetrate and fertilize the egg) and are no longer reproductively viable.

Temporal Synchronization

Temporally synchronizing insemination with ovulation among different species has been achieved through the evolution of four different breeding patterns: seasonal breeding, cyclical breeding, induced ovulation, and continuous breeding.

Seasonal Breeding

Patterns of *seasonal breeding* are triggered by changes in the photoperiod (i.e., changes in the amount of light relative to the amount of dark in a 24 h period) which trigger the release of sex hormones, and as a consequence, breeding only occurs during a relatively narrow seasonally specific period of time. Seasonal breeding evolved not only to synchronize insemination with ovulation, but among species that are displaced to the north or south of the equator it serves to synchronize the production of offspring with a period of time during the year that will give offspring enough time to acquire the necessary resources to survive their first winter (see Gallup et al. [in press](#)). Although humans are no longer seasonal breeders, a disproportionate number of human babies are born in the spring and if you count back in time by 9 months to determine when they were conceived, humans show a vestigial tendency toward summer breeding (Timonen and Carpen [1968](#)). With the invention of artificial illumination, humans have unwittingly created a “continuous summer” where they are exposed to ± 16 h of light day in and day out, 365 days a year (Gallup et al. [in press](#)).

Cyclical Breeding

Other species employ patterns of *cyclical breeding* where breeding proclivity is under the control of endogenous mechanisms that trigger the release of hormones on a recurring cyclical

basis. Among many species that are affected by cyclical breeding, female sexual receptivity is usually restricted to the fertile/ovulatory phase of the cycle which serves to synchronize insemination with ovulation. Among many species that engage in cyclical breeding, females produce ovulatory cues (visual, auditory, or olfactory) that signal ovulation and have a powerful effect on males by triggering sexual arousal. Cyclical breeding in humans is expressed as the menstrual cycle. Even though humans can engage in sex at any point in the menstrual cycle, growing evidence shows that women are still unwittingly subject to important menstrual cycle effects that often operate below the radar (i.e., at a subconscious level).

A classic and compelling case in point is a study conducted by Miller et al. ([2007](#)) where they tracked the tips earned on a daily basis by lap dancers as a function of where they were in their menstrual cycle and whether they were using hormonal contraceptives. Those who were naturally cycling almost doubled their tips when they were in the fertile phase as compared to the menstrual phase. Equally interesting was that naturally cycling lap dancers earned more money in tips during all phases of their menstrual cycle than those on hormonal contraceptives. While all the lap dancers were acutely aware of day-to-day variation in their tips, none had any idea that where they were in their cycle or that using hormonal contraceptives made a difference.

Taking hormonal contraceptives not only diminishes your attractiveness and your libido, it also puts many evolved and otherwise adaptive choice mechanisms on hold. Couples who met when the woman was on the pill are far more likely to have children who are immunocompromised, i.e., at greater risk of a variety of common ailments (Birnbaum et al. [2016](#)). Moreover, women who discontinue using hormonal contraceptives to get pregnant often discover that they are living with a man they feel they no longer know and who they find less sexually attractive (Roberts et al. [2012](#)).

Induced Ovulation

A relatively small number of cyclical breeders also exhibit *induced ovulation*. Cats and rabbits, for example, are induced ovulators. As anyone with an adult female cat that has not been neutered can testify, when cats go into heat (which means they are in the fertile phase of their cycle), their behavior changes dramatically. But unless your cat has sex with another cat while she is in heat, she will not ovulate. Among induced ovulators, vaginal stimulation is required for ovulation to occur. Induced ovulation provides for the more efficient use of eggs.

Continuous Breeding

Although humans are still affected by subtle effects of seasons and cycles, women no longer produce vivid, easily discernable ovulatory cues. As a consequence, human sexual behavior is no longer driven solely by such considerations and humans approximate what are called *continuous breeders*. In the absence of ovulatory cues, the problems posed by synchronizing insemination with ovulation become more acute. Engaging in high-frequency sex that is independent of seasons and cycles represents an evolved statistical solution to this problem, i.e., high-frequency sex that occurs over an extended period of time will eventually lead to instances in which insemination and ovulation will be coincidental. Thus, patterns of continuous breeding represent an evolved solution in humans to the problem posed by the loss of ovulatory cues.

Spatial Proximity

In addition to the need for temporally synchronizing the release of male and female gametes, spatial proximity is also important.

Internal Versus External Fertilization

The problem of achieving proximity in space for gamete release can be illustrated by the distinction between external versus internal fertilization. Among many species of fish, the male and female simply release their genetic material into the environment in sufficiently close proximity to one another that the sperm from the male will intermingle with and fertilize some of the female's eggs. For species that live in moving water (i.e., rivers and streams), the male must position himself immediately upstream from the female for spawning so that his sperm will drift downstream to come into close proximity to the eggs being released by the female. With the emergence of internal fertilization, sperm are deposited inside the female's reproductive tract where it is in much closer proximity to her eggs. This represents a more efficient use of sperm and eggs. The penis evolved primarily as an internal fertilization device (but see Gallup et al. ([in press](#)) for other derived functions that the human penis serves).

Spatial Proximity and Insemination

Most people do not realize that human evolution has also put a premium on spatial proximity when it comes to insemination. With the assumption of an upright posture and bipedal locomotion, the woman's reproductive tract has changed from what used to be a parallel orientation with respect to gravity when we were quadrupeds to what is now a perpendicular orientation where it is poorly suited for sperm retention (Gallup and Suarez [1983](#)). Under such conditions, natural selection may have operated to put a premium on penis length as a means of depositing sperm deep in the vagina in close proximity to the cervix as a means of promoting sperm retention. Consistent with this analysis, the human penis is largest among the great apes, which are our closest living relatives (Short [1979](#)).

Conclusion

Sexual reproduction requires the release of male gametes to occur in both temporal and spatial proximity to the release of female gametes in order for conception to occur. Temporal contiguity has been achieved by the evolution of four distinct breeding patterns: seasonal breeding, cyclical breeding, induced ovulation, and continuous breeding. Along with restrictions on timing, spatial constraints have led to the evolution of internal fertilization, and in the case of bipedal, humans may have contributed to a reproductive advantage associated with a longer penis. When it comes to reproduction, it is not simply a question of whether to breed or not to breed, it is a question of when and where.

Definition

Reproductive value is defined as the contribution of an individual to the future gene pool of a population. Because reproductive value mediates the fitness costs and benefits of social behavior, it plays a key role in the adaptive value of aggression.

Introduction

Most populations are structured into classes. Classes are features of organisms and their environment that influence the portion of their lifetime reproductive success that is not directly ascribed to the action of genes associated with the trait of interest. In such populations, individuals can transition between different classes over the course of their lifespan, and, while in each class, they generate fitness that contributes to their lifetime reproductive success (Frank 1998). The relative weight of each class on the lifetime reproductive success of an organism is given by its reproductive value, which measures the contribution of individuals in any given class to the future gene pool of a population (Frank 1998). Class structure and reproductive value influence the evolution of traits. The impact of traits on lifetime reproductive success depends on their effect on the fitness of each class, with each of these effects being weighted by the reproductive value of the corresponding class. Thus, classes with high reproductive value will in general contribute more to the action of natural selection than classes with lower reproductive value (Frank 1998).

Class structure and reproductive value mediate the evolution of social traits, including aggression (Rodrigues and Gardner 2013). In populations without class structure, Hamilton's rule, the condition governing the evolution of social behaviors, is given by $-c + rb > 0$, where c is the cost of the social behavior to the actor, r is the coefficient of relatedness between the actor and the recipient, and b is the benefit enjoyed by the recipient of the behavior (Hamilton 1964). Hamilton's rule tells us that an altruistic act will evolve if the cost to the actor is sufficiently low and the benefit – depreciated by the coefficient of relatedness – is sufficiently high. Although Hamilton's rule is often described in terms of an altruistic act, it explains the evolution of any type of social behavior. These behaviors can be classified into four main types, depending on the sign of the fitness costs and benefits: when $c > 0$ and $b > 0$, the behavior is denominated altruistic; when $c < 0$ and $b > 0$, the behavior is

denominated cooperative (or mutually beneficial); when $c < 0$ and $b < 0$, the behavior is denominated selfish; and when $c > 0$ and $b < 0$, the behavior is denominated spiteful. Most often aggression is a selfish strategy because it benefits the aggressor and imposes a cost on the victim, but it can also be a spiteful behavior in which both the aggressor and victim suffer costs.

This classical formulation of Hamilton's rule assumes that the actor and recipient belong to the same "class." That is, the only difference between actor and recipient lies in their genes, a difference that is encapsulated in the coefficient of relatedness, r . More generally, actor and recipient can differ in many respects, including age, state, and/or sex (Rodrigues and Gardner 2015, 2016; Rodrigues 2018). These differences matter for the evolution of social behavior, and they are partially captured by reproductive value. When social partners are in different classes, Hamilton's rule can be written as $v_A C + r v_R B > 0$, where C is the survival (or fecundity) cost to the actor; B is the survival (or fecundity) benefit enjoyed by the recipient; v_A is the reproductive value of the actor (or actor's offspring); and v_R is the reproductive value of the recipient (or recipient's offspring; Rodrigues 2018). This form of Hamilton's rule highlights that reproductive value mediates both the costs experienced by the actor and the benefits enjoyed by the recipient.

Reproductive value is typically measured as age- and sex-specific averages at the population level and is calculated from age-specific fertility and mortality rate curves. If we assume a stationary population, reproductive value at age x is given by $v_x = \sum_{y=x}^{\infty} (l_y/l_x) m_y$, where m_y is the fertility rate at age y and l_x (or l_y) is the probability that an individual survives to age x (or y), with $l_x = \prod_{a=1}^x (1 - \mu_a)$, in which μ_a is the mortality rate at age a (Fig. 1).

While the reproductive value curves of men and women are similar, there are important differences that have an impact on sex-specific patterns of aggression. In men, reproductive value rises and peaks later in life, and once it attains its peak, it slowly decreases as men enter old age. In women, the pattern is different: they achieve

Reproductive Value and the Evolution of Aggression, Fig. 1 Hypothetical fertility, mortality, and reproductive value curves for women and men as a function of age. Age of peak reproductive value is less than age of peak

fertility. Typically, the reproductive period of women starts earlier than the reproductive period of men, while the reproductive period of women finishes earlier than the reproductive period of men

peak reproductive value earlier in life, and unlike men they experience menopause – i.e., the early cessation of reproductive function – which is characterized by a sharp decline in reproductive value after they reach their 40s or early 50s (illustrated in Fig. 1).

The total reproductive value in a population is shared between the sexes. In humans, an offspring receives half of their genes from her father and half from her mother, and therefore 50% of the gene pool of the population is composed of paternally derived genes and 50% of maternally derived genes. As a result, approximately half of the total reproductive value in a population is accrued to males (i.e., = 0.5), while the other half is accrued to females (i.e., = 0.5). This introduces intra-sexual competition for reproductive shares within each sex but also intersexual competition over control of fertility shares and breeding resources (Fig. 2).

Natural selection favors the evolution of aggression when it increases mating opportunities or breeding resources or, more generally, when it increases the reproductive value of the aggressor. Because many forms of aggression affect multiple individuals, it is helpful to consider a form of

Hamilton's rule that reflects such scenario. In particular, if we consider that the behavior involves an actor and n recipients, we can then write $-Cv_0 + \sum_{i=1}^n B_i v_i r_i > 0$, where v_0 is the reproductive value of the actor, B_i is the effect of the behavior on the fitness of the recipient "i," v_i is the reproductive value of the recipient "i," and r_i is the relatedness between the actor and the recipient "i."

Hamilton's rule and the reproductive value curves of humans allow us to make several predictions. First, when resources are limited, those with lower reproductive value are at higher risk of being victims of aggression. Second, individuals with high reproductive value are at risk of experiencing aggression that targets their reproductive potential. Finally, those with more future reproductive value weigh less their current fertility. Here, we explore some examples of how these and other general predictions can generate some insights into the evolution of aggression in human societies.

Aggression by males – In humans, mothers devote a large share of their time and resources to caring for their dependent young (Sear and Mace 2008). While the absence of any other family member has relatively little effect on the

Reproductive Value and the Evolution of Aggression, Fig. 2 Costly aggression, in which an actor pays a cost $C (> 0)$ to inflict a cost $B_1 (< 0)$, may evolve if this gives access to additional mating opportunities and/or reproductive resources $B_2 (> 0)$. Competition for breeding resources can occur against individuals of the same sex

(intra-sexual competition, panels A and B) or against individuals of the opposite sex (intersexual competition, panel C). Males (or females) usually compete with other males (or females) for breeding opportunities. The benefits of aggression (B_2) tend to increase with the reproductive value of the individual of the opposite sex

survival of young, without a mother offspring survival drops significantly (Sear and Mace 2008). Because birth is followed by this intensive period of maternal care, it often takes 4–5 years between births. Under monogamy, this period of parental care can be harmonious: the genetic interests of both mother and father are closely aligned, and, therefore, they have a shared interest in the survival and well-being of current offspring. However, human societies are often characterized by serial monogamy and/or some degree of promiscuity. In such cases, a stepfather may be present, while a mother is still caring for the dependent young of a previous relationship. Because stepchildren and stepfathers are normally unrelated, the dependent young can represent a cost to the fitness of stepfathers. Further, the younger the offspring, the longer the period of maternal care before mothers can conceive again and therefore the longer the period before stepfathers can sire offspring of their own. Thus, the young age of stepchildren can increase the probability of abuse by stepfathers.

The age of the mother also influences the probability of abuse by stepfathers, which is higher when mothers are relatively young. First, younger mothers have higher future reproductive value. Second, reproductive value of infants (and children) can be low. Thus, the loss of a young

offspring may have a marginal impact on the lifetime reproductive success of a younger mother. Some evidence supports these predictions. First, the presence of a stepfather in the household increases the probability of child abuse. In a Canadian population, for instance, less than 1 in 1,000 children were victims of child abuse if they lived with their natural parents, but more than 12 in 1,000 were victims if they lived with one stepparent (Daly and Wilson 1988). Second, the risk of infanticide by a stepparent is significantly higher when children are within the 0–5 age range but drops significantly among older children (Daly and Wilson 1988). Finally, children of younger mothers are most at risk of violence (Daly and Wilson 1985; Nobes et al. 2019).

Aggression by females – In general, high relatedness between mother and offspring reduces the potential for maternal-offspring conflict. However, as we have seen above, other factors also play a role in mother-offspring interactions, and under some social and environmental conditions, maternal neglect of offspring – and other forms of aggression – is more likely to occur. For instance, whenever future reproductive opportunities are lost because of ongoing investment in current offspring, neglect of current offspring may allow parents to redirect resources to future offspring. This tendency may increase when current

Reproductive Value and the Evolution of Aggression, Fig. 3 The fitness costs of aggression are lower when directed toward a lower-reproductive value (lower-rv) offspring (i.e. offspring 1), and therefore lower-rv offspring are at risk of experiencing higher levels of

aggression ($z_L > z_H$). Mothers may decide to allocate more resources to future children when a current child has low reproductive value, for instance, due to a congenital disorder

offspring are of lower quality (i.e., lower reproductive value) owing to genetic factors, such as heritable diseases, or to nongenetic factors, such as chronic diseases caused by parasite infections (Fig. 3). Second, postponing childbearing may allow parents to accumulate social and economic capital, which they can invest in future offspring. Older women, by contrast, may not have this option.

As menopause approaches, pregnancies become increasingly unlikely, and therefore current offspring are relatively more valuable for older mothers. As a result, we expect older mothers to be less likely to neglect their current children than younger mothers. Evidence that supports these predictions is diverse. Infanticide rates are highest among mothers that give birth before their 20s; and infanticide rates among mothers that give birth in their early 20s are higher than those of mothers that give birth in their late 20s or early 30s (Daly and Wilson 1988). Further, older primiparous mothers are more likely to invest in high-risk (i.e., premature) children than younger or multiparous older mothers (Beaulieu and Bugental 2008).

Sexual coercion – While in most cases there is mutual consent between sexual partners, in others some degree of sexual coercion may occur. There are certainly costs associated with such violent behavior but – from an evolutionary perspective –

there are also potential fitness benefits. For instance, the benefits of sexual coercion increase with the fertility and reproductive value of the victim. Coercion of infertile victims renders zero benefits, but the potential costs will still be large, and therefore such behavior can seriously compromise the fitness of aggressors. Because fertility and reproductive value tend to be higher among younger women, they are at a higher risk of being the target of aggressors. Some evidence supports these predictions. First, the age group that is more at risk of rape is the 20–24 age group (Thornhill and Thornhill 1983). Second, in a study among forager-farmers, a key predictor of wife abuse was the young age of the wife (Stieglitz et al. 2012). Wives in their early 20s are almost twice as likely to be abused than wives in their mid-30s (Stieglitz et al. 2012). Finally, a statistical analysis has found that of those women that were victims of robberies, younger women were also more likely to be victims of rape (Felson and Cundiff 2012).

Neglect of elders – If reproductive value was the only measure of value, then elders would have little or no value for societies. Elders are users of a community's resources, and this can create a tension between elders and other members of the community. Despite this tension, in many societies, elders are revered and therefore there must be factors that promote a positive view of old age.

Naturally, how societies perceive old age depends on culture. However, biological considerations may also contribute to a positive perception of old age. While the reproductive value of elders is zero, their behavior often increases the reproductive value of daughters, sons, and grandchildren. For instance, the survival and well-being of young depend on to a certain extent on the care provided by grandparents (Sear and Mace 2008). Despite this, the lower reproductive value of elders, the fragmentation of extended families in contemporary societies, and the societal cost of old age may sometimes contribute to the neglect of elders, which, in some cases, can lead to self-harming behaviors among this age group. Old age seems to be especially taxing in males. While men are more likely than women to commit suicide across all age groups, the difference is highest at older ages, when men are more than seven times more likely to commit suicide (Kruger and Nesse 2006). Moreover, a cross-cultural study found that male suicide rates increase significantly at old age, especially in harsh environments (Syme et al. 2016).

Male-male aggression – As we have seen above, the reproductive value of males and females follow similar patterns: they increase rapidly after maturity, peak during middle age, and decrease as men and women approach older age (Fig. 1). There is, however, an important contrast: variance in reproductive value is greater among males. High variance in male reproductive value occurs because some men father many offspring, while others father few or none, a discrepancy that is less pronounced among women. Variance in reproductive value emerges because of the hierarchical structure of human societies: those men that attain higher status tend to father more offspring (Chagnon 1988). Because of the correlation between status and reproductive success, competition for status, which can take the form of aggression, can be fierce. Males are willing to pay the cost of aggression – as aggressors risk injury and even death – if aggression increases their status and consequently their mating success. Naturally, mating success can only be translated into reproductive success if the male is fertile. Thus, it is perhaps not surprising that aggression

is more prevalent among younger men, when male fertility is at its peak. A statistical analysis of contemporary societies shows that homicide among men increases rapidly after sexual maturity and is significantly larger among men than among women (Daly and Wilson 1990). In tribal societies, aggression can be positively correlated with number of wives and children (Chagnon 1988; Glowacki and Wrangham 2015), which suggests that male-male aggression may have been adaptive in our ancestral environment.

Female-female aggression – While intra-sexual competition is more salient among men, female-female competition is also widespread, with women competing for resources as well as mates. Intra-sexual competition among women can be indirect, which is usually manifested in the form of displays or gossip, but it can also be direct, as women may resort to verbal abuse and even physical aggression (Campbell 2013; Stockley and Campbell 2013). The proclivity for indirect aggression is similar between men and women (Hess and Hagen 2006), but women tend to target features of other women that are correlated with fertility and/or reproductive value. For instance, women tend to derogate more the appearance and promiscuity of other women than men do (Buss and Dedden 1990). Sometimes, male preferences may mediate competition among women. For instance, because younger women have higher fertility rate and reproductive value, men tend to prefer younger women. As such, younger women can be at higher risk of aggression from older women (Campbell 2013).

Conclusion

Reproductive value provides a measure of an organism's value to the evolutionary process, and therefore it mediates the costs and benefits of social behavior, including aggression. Reproductive value can explain and predict a vast number of human behaviors. It can predict the intensity of aggression that occurs within each sex, between the sexes, and between individuals in different condition and of different age. While

aggression may have an evolutionary basis, human societies have undergone major transformations over the past few millennia, and therefore contemporary expressions of aggression may not be adaptive. Ultimately, to prove adaptation we must find correlations between behavior and fitness that are consistent across a wide range of cultures (Stearns and Rodrigues 2020). Finally, aggression is not an inevitable outcome hardwired in the genes of organisms. Aggression is often a context-dependent behavior, and it depends on multiple cultural and biological factors, which include reproductive value. Understanding the biological factors that mediate aggression can ultimately be used to reduce aggression both within and between societies.

Definition

The degree of success that individuals of a species are able to achieve by producing offspring. Male reproductive success tends to be limited to the number of matings one can achieve, while female reproductive success tends to be limited by the number of eggs that can be produced.

Introduction

The term reproductive variance in biology refers to the distribution of reproductive success that characterizes a species or sex within a species. Among most vertebrate species, the reproductive variance of males is higher than the reproductive variance of females. Robert Trivers' proposed parental investment theory, according to which anisogamy and internal gestation result in a higher minimum obligate investment in offspring on the part of females. According to Trivers, a host of mating-related behaviors are the result of the disproportion in obligate investment between males and females. Angus Bateman investigated the difference in reproductive variance between males and females while studying *Drosophila melanogaster* (fruit fly). Bateman observed that very few females failed to reproduce, while a much larger proportion of males failed to reproduce. Additionally, the amount of copulations was a stronger predictor of reproductive success for

males than for females. From these observations, Bateman's principle was formulated which states that reproductive variance is greater for males than for females. Finally, modern research has found this relationship to hold constant among the majority of animal species; however, there has also been research on a few species in which these sex roles are reversed. Additionally, the field of evolutionary psychology has utilized the theoretical contributions of Bateman and Trivers to explain a range of human mating-related behaviors, such as sex differences in responses to an infidelity.

Sexual Selection

Charles Darwin proposed natural selection as the mechanism by which evolution occurs in his work *On the Origin of Species by Means of Natural Selection* (Darwin 1859). However, Darwin noted that some features found in nature did not appear to confer an advantage to an organism's survival. According to his theory of natural selection, the plumage on a male peacock should not be selected for it is metabolically costly and likely to attract predators while not conferring any benefits to survival. Darwin followed his first work on evolution with *The Descent of Man, and Selection in Relation to Sex* in which Darwin proposed a second mechanism by which traits are selected, sexual selection (Darwin 1871). According to Darwin, certain features, such as the peacock's tail, evolved because they conferred benefits to mating rather than survival. There are two complementary processes by which sexual selection occurs: intrasexual competition and intersexual selection. Intrasexual competition is the direct or indirect competition between conspecifics of the same sex in which the result of the competition leads to differential access to mating opportunities. These competitions can take the form of direct aggression, production of ornamental features, etc. For intersexual selection to occur, individuals of one sex must have a general consensus on the traits that are preferable in members of the opposite sex and will choose those members differentially based on those preferences. For

example, the bright plumage that male peacocks display is selected because female peacocks are more likely to choose males based on the number and arrangements of eyespots on their train (Petrie and Halliday 1994).

Bateman's Principle

Angus Bateman (1919–1996) was an English geneticist who received his B.S., Ph.D., and D. Sc. from King's College, London (Dewsbury 2005). In 1948, Bateman reported a study investigating the reproductive success of *Drosophila melanogaster* (fruit fly) males and females (Bateman 1948). The principal report of Bateman's 1948 study would later be defined as Bateman's principle by E.O. Wilson (1975) to mean that "the variance of reproductive success is greater in males than in females" (Wilson 1975, p. 325).

In Bateman's 1948 study, he set out to provide what he referred to as more systematic and statistical support for sexual selection as described by Charles Darwin. Bateman put groups of equal numbers of males and females from different strains of the *D. melanogaster* into small bottles and then allowed them to mate and lay eggs for several days. Bateman tracked the success rates of males and females by mixing different strains of the fly who had distinctly different chromosomal markers that would allow for him to identify the fertility (or reproductive success) of the males and females in the groups. First, Bateman identified that there was a greater variance in the reproductive success of males compared to females. For example, only 4% of all of the female flies failed to reproduce contrasted with 21% of the males failing to reproduce. Bateman identified this as a "sign of intra-masculine selection" being that sexual selection is working primarily on males. Second, Bateman found a positive linear relationship between male fertility and the number of copulations achieved, while female fertility and number of copulations were very weakly correlated. Bateman referred to this second phenomenon as the "cause of intra-masculine selection" since the success rate of

males to produce offspring is limited by the number of copulations (and inseminations) that occur, while the limiting factor of female reproductive success is the number of her own sex gametes that are available to be inseminated. Bateman argued that the existence of these two pieces of evidence, (1) the differential of males who are able to successfully copulate compared to the number of females who are able to copulate and (2) the number of copulations with novel sex partners that predicts greater success in males than in females, indicates that the pressures of sexual selection will have a stronger effect on males than on females. For example, in many species of polyandrous elephant seals, females usually have at least one pup in their lifetime, while the majority of male elephant seals father zero pups in their lifetime, while a small number of alpha-male seals father the majority of offspring (Hoelzel et al. 1999).

Parental Investment Theory

A parent's investment of resources in an offspring often comes at the expense in the investment in oneself, other offspring, or potential mating opportunities. Robert Trivers (1972) proposed parental investment theory. According to Trivers, the sex that has the higher minimum obligate investment in offspring will be more selective in their mating. As a corollary, the sex that has the lower minimum obligate investment will tend to engage in more intersexual competition for mates. Investment in offspring occurs at several levels. Most sexually reproducing species are characterized by anisogamy, meaning the gametes produced are not equivalent. In humans, females produce of relatively large, expensive eggs, whereas male sperm is far cheaper to produce (a male will produce hundreds of billions of sperm over the course of his life). In addition to the production of gametes, females must endure 9 months of internal gestation and then breastfeeding in order to produce viable offspring. Males, however, need only to minimally invest in the act of copulation in order to produce viable offspring. According to

Trivers, this difference in gamete size and gestation begets further differences in investment as the offspring continues to age. This difference in investment between the sexes is predicted to lead to a mating pattern that is different for males and females. Females, due to their higher investment, will tend to be more selective with their mating opportunities in order to prevent the costs of making a poor mate choice. Because females will be more selective with their mating decisions, males are expected to be more likely to compete among themselves in order to gain mating opportunities. This pattern of mating strategies between the sexes is referred to as the ardent male-coy female hypothesis.

Modern Research

Bateman's principle, the theory of sexual selection, and reproductive variance have been demonstrated and explored in a number of different species, ranging from humans (McKean and Nunney 2005; Brown et al. 2009), the sex-reversed pipefish (Jones et al. 2000, 2005), the rough-skinned newt (Jones et al. 2002), redback spiders (Andrade and Kasumovic 2005), bank voles (Mills et al. 2007), wild turkeys (Krakauer 2008), red jungle fowl (Collett et al. 2014), seed beetles (Fritzsche and Arnqvist 2013), and hermaphroditic freshwater snails (Pelissie et al. 2012) to name a few.

Bateman's principle has been expanded to explain a diverse number of species ranging from plants and hermaphroditic species (Arnold 1994) as well as to different mating systems and sex roles among humans (Brown et al. 2009) and to species where the sex roles are reversed (Jones et al. 2000, 2005). In all of these unique circumstances, male and female psychology and behavior tend to follow trends where males have more variability in their access to females and in their ability to successfully reproduce. Mating frequency and control over their partner's mating availability (in applicable species) are significantly better predictors of male success than female success. Sex-reversed species are seen as exceptions that prove the rule in that pregnant

males tend to become choosier and rely less on access to mating than their female counterparts (Jones et al. 2000, 2005) who compete mating access at a similar rate to the non-sex-reversed species.

Bateman's principle has contributed to a significant line of research in human evolutionary psychology, especially when taken into consideration in concert with parental investment theory, for example, men being less discriminatory in choosing mates than women (Buss 1989; Buss and Barnes 1986) and women having the most intense discrimination when choosing potential long-term partners (Buss 1994; Townsend et al. 1995). Miner and Shackelford (2010) review many of the aspects of sex-predicted behavior related to reproductive variance. Men's preference for younger, more attractive partners, women's preference for partners with resources and partners who are willing to invest, and men engaging in behaviors to prevent, correct, and anticipate their partner's potential infidelities are examples of men and women utilizing strategies that are consistent with the predictions laid out by Bateman's principle. Men are, in general, likely to be more upset by the prospect of their partner committing a sexual infidelity (increasing the risk of cuckoldry and their partner's fertility), while women are generally more upset by the prospect of their partner committing an emotional infidelity (increasing the risk of partner defection and a loss of investment) (reviewed in Bjorklund and Shackelford 1999). Relationships are more likely to be dissolved over issues of infidelity and infertility (reviewed in Miner and Shackelford 2010). Bateman's principle predicts that males are more likely to be concerned with having access to females, while females will be more interested in discriminating high- and low-quality males. Indeed, men tend to most attuned to the issues of their partner's fertility state and are reflected in how they pursue, maintain, and end relationships as well as how they become emotionally distraught and where they place their attention. Women tend to place more of their attention to the ability of their partner to invest in long-term relationships and provide for a family.

Conclusion

The reproductive variance of a species and sex within a species is an important component in determining the mating strategies that the organisms within that group adopt. Bateman's principle outlines a pattern in which males tend to experience greater reproductive variance than females do. Indeed, this pattern has been found in the majority, but not all, of the animal species that have been studied. In addition to Bateman's theoretical contribution, Robert Trivers explained the reason why the sexes within most species demonstrate differences in reproductive variance: obligate minimum investment. According to Trivers, the obligate minimum investment in offspring is much higher for female. Among humans, females produce a much larger, more costly gamete, are required to endure 9 months of internal gestation, and then must continue to breastfeed and care for the offspring after birth. Due to the difference in reproductive variance and obligate minimum investment, males and females display differences in their mating behaviors and strategies. These sex differences have been studied across a range of species and, in the field of evolutionary psychology, have been documented in humans as well. For example, human females tend to be more discriminant when selecting potential long-term mates than human males do (Buss 1994).

The families of suicide attackers might benefit reproductively from the increased reputation associated with having a family member celebrated as a martyr, suggesting a potential evolutionary motivation for suicide attack.

Introduction

Suicide terrorism might yield heightened family reputation and status within local communities, providing an avenue through which suicide terrorists might generate benefits to their genetic kin. Though this is an interesting hypothesis, there are currently no studies that measure the mating or reproductive outcomes of the kin of suicide terrorists as a function of increased reputation.

Theoretical Overview: Suicide Terrorism and Reputational Benefits to Kin

Research conducted in several Muslim nations indicates that identity based on collectivism as opposed to individualism is associated with greater support for terrorism (Kruglanski and Orehek 2011). The cultures of the Middle East and circum-Mediterranean region are often deemed honor cultures where many social norms and priorities are constructed around reputation maintenance and shame-avoidance (Peristiany 1965). Employing agent-based modeling, Nowak et al. (2016) demonstrated that honor cultures could be adaptive under conditions wherein institutional authority is weak and resources are scarce. Thus, honor-based strategies, i.e., retaliation against aggressors in defense of one's own and family's reputation and honor, might be an effective and evolutionarily stable strategy. An abundance of evidence suggests that suicide is used in a geographical array of "honor cultures" to reestablish one's own or one's family's honor (Osterman and Brown 2011). Likewise, motivations for suicide terrorism include the defense of honor of one's people and homeland; moreover, suicide terrorists are often celebrated as "martyrs" (Hafez 2006). The reputational benefits obtained by the deceased in these instances appear to extend to their kin, and theoretically, the kin might receive reproductive benefits (e.g., greater access to high status mates) as a result of the death of their loved one as a perpetrator of a suicide attack.

Hafez (2006) contends that in a rational-choice approach to suicide terrorism, the honor afforded the families of martyrs might factor into cost-benefit calculations, noting that in this perspective the social benefits for the suicide terrorist alone cannot be considered “rational” since he or she will not survive to see those benefits. In this sense, the reputational argument of suicide terrorism must factor culture into consideration. The veneration of martyrs, Hafez (2006) argues, will occur in a society when the following conditions are met: (1) the justification and celebration of martyrdom through tradition and symbolic representations; (2) the promotion of violence and martyrdom by recognized cultural authorities (e.g., local leaders or institutions); and (3) the society feels victimized or threatened by an outside aggressor.

Conclusion

Numerous studies demonstrate that high status correlates with reproductive success. Though reputational benefits are anecdotally cited as a potential motivator for suicide attack, there are currently no studies that even quantify reputation, nor measure how those might translate into reproductive benefits for the kin of suicide attackers.

Reputation and Altruism

Definitions

Reputation is used to mean a publicly available index of past behavior.

Altruism is used to mean a behavior that is costly to the individual and benefits another individual or group of individuals. Here it is taken to include behaviors that have some cost, but which may have a net benefit due to the responses of others.

Introduction

Why might individuals help others? Evolutionary psychologists seek adaptive answers to this question by investigating how helpers get something

back. This becomes most challenging when individuals are not kin and do not get a return through direct reciprocation. One way in which helping might actually be self-interested is if others learn about the helpful behavior and in consequence act preferentially toward you. Thus it may pay to care about reputation – about behavior not just with a partner but in a social setting where others may have access to some index of past behavior. It is apparent that people act more altruistically when they are being observed, e.g., people are more charitable in the presence of group mates (Bereczkei et al. 2007). This tendency is found even when the “observer” is simply an image of “watching eyes” (Bateson et al. 2006). Furthermore, people are viewed in a better light when they act altruistically, gaining in reputation (Hardy and Van Vugt 2006). Research has then focused on what benefits individuals get from this boost to reputation.

Altruistic Reputations

Individuals who have been seen to be altruistic might be less likely to be punished for contributing little, or may be more likely to be rewarded. Focusing here on the possible rewards, these may come through indirect reciprocity or through reputation-based partner choice. Indirect reciprocity is where people are more likely to help those who help others. Through this mechanism, altruism pays when it leads to an increase in altruism received. The best known models of this process invoke what is termed “image scoring,” a simple index of past donation behaviors (Nowak and Sigmund 2005). Laboratory experiments show that people do indeed tend to give more to those with higher image scores (Wedekind and Milinski 2000).

Theories of reputation-based partner choice consider instead that when someone is altruistic, they are not just helping another individual; they are displaying something about themselves. Costly signaling theory shows how being altruistic can honestly indicate high quality to an observer since the costs of altruism can make it pay off for high-quality individuals but not for

those with fewer resources (Gintis et al. 2001). Economic experimental games show that people will display greater altruism in order to make themselves more attractive partners and that this pays off in the long term from engaging in profitable partnerships (Sylwester and Roberts 2010). The increase in altruism associated with competition for partners has been called competitive altruism (Roberts 1998). Using an altruistic reputation to signal to potential social partners may explain phenomena such as charitable giving and willingness to contribute to public goods games.

An altruistic reputation may also be driven by sexual selection. For example, people are more likely to be altruistic to attractive members of the opposite sex in economic games (Farrelly et al. 2007) and also when giving to women seeking sponsorship for charities (Raihani and Smith 2015).

Conclusion

It is apparent that being seen to be altruistic can be in an individual’s own interests, and the benefits of reputation building may be a powerful explanation for altruism in humans.

Reputation as a Context for Men's Aggression Against Men

Definition

An individual's reputation refers to knowledge others share about that individual. Aggression can be used to manage one's reputation or influence the reputation of others.

Introduction

Research suggests that people are generally concerned with how aggressive other individuals are. For example, researchers have shown that people are good at detecting angry facial expressions (Hansen and Hansen 1988), can form first impressions of an individual's aggressiveness after looking at their face for 0.01 s (Willis and Todorov 2006), and usually judge people on warmth before judging them on other traits

(Fiske et al. 2007). Furthermore, people (especially men) also seem interested in displaying their own aggressive tendencies. For instance, experiments illustrate that men may act aggressively to assert their manhood when it is challenged (Bosson et al. 2009). Also, in cultures of honor, aggression is often used by men as retaliation after being offended (Nisbett and Cohen 1996). The propensity to track how violent other individuals are, as well as the drive to show one's aggressiveness, sets the stage for the emergence of reputations for aggression in human societies. This entry will use an evolutionary perspective to explore why people care about aggressive reputations and why men seem keener on being viewed as aggressive, relative to women.

Status, Hierarchy, and Other Related Constructs

Before answering those questions, it is worthwhile to distinguish reputations from other related concepts. As previously defined, reputation refers to knowledge that others possess concerning an individual. Some of the concepts often confused with reputation include those of status, hierarchy, power, and dominance. Cummins (2005) defines status as the priority one has over access to resources. To be high status, other people must know that one has priority over resources – i.e., one must have a specific reputation. The concept of hierarchy is directly related to status, but is at a higher level of analysis. A hierarchy refers to how a group is organized in terms of the individuals' statuses. A group has a hierarchy if some individuals in the group have a higher status than others. Finally, power and dominance are associated with how people interact as opposed to their standing in a group. Keltner et al. (2003) define power as an individual's ability to influence other individuals' states by granting or withholding resources or administering punishments. Dominance refers to the power relationship between two people. A person is dominant if they have more power than the other person.

Aggression is often used to negotiate or enforce dominance, power, or status. For example, individuals can increase their status by demonstrating their aggression publically and signaling that they have more power and dominance. In this way, people can use aggression to shape their reputations. Studies on the aggressive behaviors of men from cultures of honor exemplify this: Nisbett and Cohen (1996) report how men from the South of the United States (which has a stronger culture of honor than other regions of the United States) are more likely to respond aggressively when insulted by another man. Furthermore, people in these cultures usually give more weight to hierarchies, and men strive to maintain their status through demonstrations of power and dominance. While status or power afforded by aggressive reputations may seem intrinsically beneficial, their importance throughout (and before) human history was not due to intrinsic benefit but because of the consequences they had for an individual's fitness. Below, some adaptive functions of aggressive reputations are examined.

Accessing Resources for Survival

In hunter-gatherer tribes, which were the most common form of social organization during human evolution, labor was often divided among tribe members (Villotte et al. 2010). Although most of these societies were relatively egalitarian (primarily the nomadic tribes) and the fruits of their labor may have been shared throughout the tribe, those who had the means to occasionally access a larger share of that food (especially in times of scarcity) would be more likely to survive and provide resources to their kin. Aggressive interactions might have been an effective strategy to take food from others, and reputations may play an important role in these interactions.

From the perspective of those who are not aggressive, keeping track of who has a reputation for aggression can be extremely beneficial. One can avoid losing food by hiding it from them; one

can also choose to forfeit food preemptively to avoid getting injured in a confrontation or to gain an aggressive individual's favor. Those who are known to be aggressive also benefit from keeping track of other's reputations. They can target their efforts toward less aggressive individuals and be vigilant of those who are more aggressive than them. In addition to tracking reputations, those who are aggressive benefit from managing their own reputations. Directly attacking others in public may be an effective way of achieving this; however, merely threatening others (especially those who already have reputations for being aggressive) may also create a reputation for aggression while reducing the risks of injury associated with actual violence.

Accessing Mates

A notable feature of aggressive reputations is that men are generally more concerned with them than women. While this sex difference is pronounced in cultures of honor (Nisbett and Cohen 1996), men tend to be more aggressive than women across cultures. Daly and Wilson (1988), for example, famously showed that men are much more likely than women to commit homicide. Archer (2004) extended this result to other measures of aggression in real-world contexts. He also found that the sex difference in aggression occurred from early childhood on.

Evolutionary psychologists commonly explain this sex difference using sexual selection theory (Buss and Duntley 2006). The theory describes the different adaptive problems faced by the sexes due to a differential energy investment in reproduction. For example, women are required to bear the energetic costs of internal fertilization, placentalation, and gestation – much steeper physiological costs than those for men. A consequence of this is that men are able to have more offspring throughout their lifetimes than women. This pushes them to invest more time and energy into mating frequently, while females devote more resources to selecting mates that will be worth their

investment. The men who are more frequently chosen as mates are more likely to pass on the genes for their reproductive strategies. Because of the competition to access as many females as they can, a fruitful reproductive strategy for men is to use aggression to increase their potential for successful competition, for example, by stealing their resources, stealing their mates, physically injuring them to deter attempts to compete for a mate, or injuring them to demonstrate strength to a potential mate. Thus, men have more incentives to be aggressive (especially among each other) than do women.

The sexual selection of aggression in men increases the value of having a reputation for aggression. Men who are known to be more aggressive (or have more capacity for aggression, such as physical formidability) are seen by women to be more suitable reproductive partners (e.g., Snyder et al. 2011). Aggressive men can also deter competitors from trying to mate with their partners, their own partners from mating with other men, and are more likely to regain former mates (Buss and Duntley 2006).

Aggression Between Groups

While the sections above focused on aggression between individuals as a means to manage reputation, the same reasoning can be applied to aggression between groups. Assaulting groups can grant similar benefits as attacking other individuals – i.e., access to resources and mates. In fact, intergroup conflicts are common among human hunter-gatherer societies and other species of primates (Wrangham and Peterson 1996). This highlights the adaptive benefits that intergroup conflicts had during human evolutionary history.

Just as individuals manage their reputations for aggression, groups can also use coordinated attacks to create a reputation for themselves. This aids groups in maintaining control over subordinate groups which are less likely to offer counterattacks and will often surrender resources at the other group's will. As argued by Sidanius

and Pratto (2001), intergroup hierarchies are an important aspect of social behavior, and people strive to justify and maintain them. Yet, as in interpersonal competition, men stand to gain more than women do by using aggressive tactics to maintain a hierarchical order of groups (Navarrete and McDonald 2014). Indeed, substantial research has shown that men more strongly prefer systems of group-based hierarchy, relative to women (Lee et al. 2011), and therefore likely have a stronger interest in maintaining their group's reputation for toughness.

Building a Reputation

As has been argued in previous sections, having a reputation for being aggressive can confer many benefits, especially to men. Given this advantage, it can be worthwhile to trick others into believing that one is more aggressive or formidable than one actually is. This way, people who would otherwise be unable to forcefully steal resources can convince others to surrender resources. However, adaptations for deception will create selection pressures for counteradaptations to detect deception. Those who detect liars do not forfeit resources unnecessarily. The end result of these selection pressures is that people only believe someone is aggressive if there are reliable indicators of aggression. These indicators are referred to as honest signals (Van Rhijn and Vodegel 1980).

Aside from actual conflict, there are many honest signals of aggression (or at least the capacity for aggression) that people use. One of them is physical formidability. Sell et al. (2009) demonstrated that people have specialized mechanisms to determine an individual's fighting ability merely by observing their face and body. Carré et al. (2009) extended these findings by showing that a person's facial width-height ratio is related to that person's aggressive behavior. In addition to physical characteristics, a person's risk-taking behavior can also indicate his/her propensity toward aggression. Fessler et al. (2014) found

that men who took more risks were estimated to be physically larger than men who did not take risks. It is likely that more physical characteristics and behavioral patterns associated with aggression are also used as honest signals. These help individuals maintain accurate reputations of their and other people's aggressiveness without engaging in costly conflicts.

Conclusion

Managing reputations for aggression has been an important activity in men's lives throughout human evolutionary history. Such reputations can confer power and status, which may lead to more material resources and access to mates. The strategy to use aggression to influence other individuals' behavior likely extends to how groups interact. Lastly, an important aspect of this strategy is that the signals of aggressiveness men send must be reliable indicators of their actual aggressiveness.

Definition

High-cost altruistic behavior, which is directed towards kin, friends, or acquaintances, and could have evolutionary origins in kin selection and/or reciprocal altruism.

Introduction

High-cost altruistic behavior takes place when the altruistic donor incurs substantial fitness costs (e.g., in terms of time, energy, resources, risking injury) when helping the recipient. The cost of altruistic helping seems to be directly associated with relatedness – we are willing to engage in higher cost help when it is directed towards close kin (Stewart-Williams 2007). The highest possible costs are paid when the altruist is risking her own life. Especially in those circumstances, we are more likely to help closely related individuals rather than friends or more distant relatives (Fitzgerald and Whitaker 2009). This kind of high-cost altruistic help is best explained by the theory of inclusive fitness, suggesting that by helping our close relatives, we are also helping our own genes.

However, people are willing to engage in high-cost altruistic acts directed towards unrelated individuals, especially to those who are considered as friends. Altruism within friendships could potentially be explained by reciprocal altruism, the idea that favors will be returned over a larger period of time. Nevertheless, when helping puts the altruist's life in danger, the likelihood of returning the favor at a later stage is reduced. In situations of heroic rescue, reciprocal altruism becomes a nonviable evolutionary explanation. It is important to understand the evolutionary roots of friendships in order to understand why high cost helping takes place between acquainted, but unrelated individuals.

Helping Relatives

According to the idea of inclusive fitness, it makes sense to help relatives if it increases their reproductive success, as by doing this, the altruist is benefitting his own genes. Research on many different species has shown that group members are more likely to emit alarm calls when closely related individuals are present.

Alarm calling is a form of a costly altruistic action, as the callers may be more easily spotted by predators, and as a consequence, could lose their lives. This kind of behavior could have been chosen for if it saves the lives of relatives. Indeed, nepotistic alarm calling is prevalent across a wide variety of species (Hollen and Radford 2009). In humans, kin may be favored over unrelated individuals in high-risk rescuing situations. A famous study by Burnstein et al. (1994) demonstrated that in hypothetical situations, humans are more willing to run to a burning house to rescue a close relative, suggesting that these kind of altruistic actions are guided by a kinship heuristic.

Helping Friends

High-cost altruistic help among friends is not based on kin selection, but possibly on the quality of the relationship, which could be a key factor in the maintenance of reciprocal altruism (Curry et al. 2013). Research has suggested that people expect reciprocation more when helping friends rather than siblings (Rotkirch et al. 2014). In extreme situations, such as in those where people are putting their lives to risk in order to rescue a friend, reciprocal altruism does not make sense as a theoretical explanation. If there is an increased likelihood of serious injury, or death, the benefits from future reciprocation are not sufficient for offsetting the costs. It has been suggested that especially women treat friends as if they were kin (Ackerman et al. 2007). If friendship is akin to kinship, high-cost altruistic rescuing behavior may not be adaptive at all, but rather, a by-product of a kinship heuristic that is applied to friendships.

Conclusion

High-cost altruistic behavior, where an individual incurs substantial fitness costs, is best explained by kin-selection. By helping closely related

individuals, direct fitness costs are offset by the increase in inclusive fitness. Research has shown that helping that involves physical pain, injury, or death is more likely to be directed towards close relatives. However, occasionally, individuals do put their lives to risk for their friends. This could be potentially explained by a kinship heuristic that is applied to friends, and may not serve an adaptive function.

Definition

Heroic rescue of strangers is an event where the rescuer puts hers/his life into risk in order to save the life on an unrelated person who the rescuer is unfamiliar with.

Introduction

Heroic rescue is a high-cost altruistic behavior that puts the life of the donor into danger while saving the life of the recipient. As such, it is an extreme form of high-cost altruism, where the ultimate cost is death (i.e., complete loss of fitness). Rescuing relatives and friends can be understood in terms of kin selection and reciprocal altruism. However, rescuing strangers is harder to explain in evolutionary terms, as this is something that has no association with future returns in terms of inclusive fitness, or returning a favor. One of the theories that has been used in trying to explain heroic rescuing of strangers is the Costly Signaling Theory, which will be briefly reviewed below.

Costly Signaling Theory and Rescuing Strangers

According to the Costly Signaling Theory, some aspects of behavior may have a function in signaling the quality of the individual to others, with the ultimate goal of changing the behavior of the receiver of the signal. Strength, stamina, and physical risk-taking have all been considered as

honest signals of quality as a sexual partner. Physical risk-taking is more typical to men than it is to women, and women prefer risk-taking men in short-term mating contexts (Sylwester and Pawlowski 2011). This indicates that risk-taking is an indicator of genetic fitness, and risk-takers are preferred by women who are shopping for good genes for their offspring.

Heroic actions often (but not always) include significant physical risk. Heroic risk-taking has been proposed as a costly signal, indicating the underlying genetic quality of the rescuer. Heroic risk includes both the elements of physical prowess and altruism, both of which are attractive to women, and have been proposed as costly signals of mate quality. Research has found that men are more likely to engage in physically risky rescues of strangers than women are (Lyons 2005), especially when their mating interests are activated (Griskevicius et al. 2007). Interestingly, some of my earlier work found that especially men from lower socio-economic backgrounds were more likely to rescue a stranger than wealthier men were (Lyons 2005). It is possible that poorer men have less to lose and more to gain in if they put their life in danger in order to rescue a stranger.

There is some evidence to suggest that women have a mating preference for heroic men. Farthing (2007) found that women perceived heroic (but not nonheroic) risk-takers as “sexy,” possibly due to genetic benefits coupled with possible status, resources, and protection that may have an association with high-cost altruistic acts. Thus, if a male engages in a dangerous rescue and survives, they may have increased mating opportunities, leading to enhanced reproductive success. Indeed, research on war veteran has found that heroic rescuers had later more offspring than nonheroic veterans (Rusch et al. 2015), pointing at the possibility that heroism has evolved through female choice for heroic males.

Conclusion

Heroic rescuing of strangers is more typical to men than for women, and women have a preference for men who risk their lives in order to rescue

another person. Evolutionarily speaking, the ultimate causes for heroic rescue of strangers could be explained by the Costly Signaling Theory, and female choice for heroic males. If a male can “afford” a heroic rescue, and survive, they may have underlying genetic quality that will be transferred to the woman’s offspring.

How similar in appearance or behavior an individual is to another, often used as a proxy for genetic relatedness.

Introduction

An important evolutionary benefit which might offset the high costs of parental investment is the opportunity for parents to maximize their genetic fitness through offspring survival (Trivers 1972). However, while women can always be certain that the offspring is genetically related to them, men risk chances of being cuckolded and mistakenly investing in biologically unrelated offspring (see ► [“Paternity Uncertainty and](#)

[Investment in Sons and Daughters”](#) chapter). In fact, the rates of paternity uncertainty are found to be approximately 1.9%. Therefore, evolutionary theories suggest that men may have adapted mechanisms to mitigate this possibility. In addition to limiting their mates’ opportunities for extra-pair copulations through mate guarding and jealousy behaviors (see ► [“Paternity Uncertainty and Investment in Sons and Daughters”](#) chapter), men may be predisposed to detecting paternity uncertainty before and after the birth of offspring. Prior to the advent of modern genetic testing, men were not able to accurately determine the paternity of a child and relied on behavioral, social, and physical cues. For behavior, fathers are theorized to evaluate mates’ behavior around the time of conception (Gray and Anderson 2010). If the father is physically away for a long period before conception, other potential mates show interest in mother, and/or if the mother seems less enthusiastic about the birth of the child, fathers may be suspicious of cuckoldry. Similarly, fathers may rely on information from other individuals about the fidelity of their mate (see below). Finally, fathers may rely on resemblance as a proxy for genetic relatedness (Volk and Quinsey 2002). In particular, fathers evaluate genetic relatedness after birth of the offspring by assessing the degree of facial resemblance with offspring (Daly and Wilson 1982; Gray and Anderson 2010).

Detecting genetic relatedness through facial resemblance is found to have modest levels of accuracy in humans (Alvergne et al. 2007). This mechanism of detecting cuckoldry and paternity uncertainty is shown to be used across cultures. For example, in polyandrous societies, such as Nepal, father-child facial resemblance is used to detect the actual father of the child (Gray and Anderson 2010). Similarly, in Sierra Leone, father-child facial resemblance is used to detect adultery. In addition to determining rates of paternity uncertainty, cues of facial resemblance to offspring are also shown to influence the degree of paternal investment.

Facial Resemblance and Paternal Investment

Mothers may also be showing positive parental behavior based on the degree of facial resemblance due to a general association between genetic resemblance and altruistic behaviors (Hamilton 1964); however, fathers have found to be more strongly influenced by cues of facial resemblance to offspring across cultures. Men are shown to emphasize cues of facial resemblance when making hypothetical investment decisions (Platek et al. 2004; Volk and Quinsey 2002). In addition, studies on actual paternal investment have found that father-child resemblance is associated with higher levels of emotional bonding and investment (Alvergne et al. 2007). Further, neurological studies have found greater activations in brain areas associated with the inhibition of negative responses when men view children's faces that are morphed with their own faces compared to non-morphed faces (Platek et al. 2004).

Adoption and Facial Resemblance

Although adoptive parents are aware of the non-genetic relationship to adoptive children, studies show that facial resemblance between adopted parents and children is still shown to be an important factor for adoption agencies and for adoptive parents (Indekeu 2015). In fact, studies have shown that the successful adoptions are more likely to occur for families with high facial resemblance between adoptive parents and children. One explanation could be that adoptive parents require social and emotional mechanisms to help support the lack of genetic relatedness to the adoptive children. Therefore, cues of high facial resemblance to adopted children may generate recognition of genetic similarity and influence altruistic behaviors in order to increase inclusive fitness (Hamilton 1964). In addition, high levels of parent-child facial resemblance may help with kinning, in which the adoptive parents make a

deliberate effort to frequently expose the adopted child to the immediate and extended family in order to increase perceptions of kinship (Volk 2011). In this case, high levels of facial resemblance between adoptive parents and adopted children may reduce social disconnections between the adopted child and the immediate and extended family. Finally, cues of facial resemblance may increase adoptive parents' investment as it may increase the appearance of genetic relatedness to others and consequently reduce social stigma associated with adopting.

Perhaps as a consequence of this, men's perceptions of facial resemblance are more strongly influenced by social factors. For example, biological mothers and maternal family are shown to ascribe paternal facial resemblance to the offspring more in the presence of the putative biological father (Daly and Wilson 1982) possibly to increase perceptions of relatedness and investment. In addition, unrelated men provide higher facial resemblance ratings between a child and a male when they are informed that an unknown man is the biological father of an unknown child (Bressan and Martello 2002). Thus, social indicators of facial resemblance may similarly influence adoptive fathers' perceptions and responses to the adopted children.

Conclusion

Children in adopted families are shown to form healthy attachments to their adopted families at similar levels to children with parents in biological families (Gray and Anderson 2010). However, high facial resemblance between the adoptive parent, especially the adoptive father, and children may increase attachment and investment. Although evolutionary theories explain why adoptive parents invest in adopted children, there is still less empirical research regarding why adoptive parents sometimes provide higher levels of investment compared to biological parents (Volk 2011). Therefore, future studies should further investigate the influence of facial

resemblance on parental investment in adoptive parents by examining individual factors, such as personality differences, in order to shed light into why some adoptive parents may be emphasizing cues of facial resemblance more than others.

Resource control; Territoriality

Definitions

Resource defense consists of controlling or denying others' access to resources, including territoriality.

Introduction

Resource defense is a broad category covering all the means by which individuals or groups actively attempt to control or deny access of others to resources, using agonistic or display behavior. This entry focuses on defense of material resources located within spatially circumscribed territories by humans, particularly in non-state societies documented ethnographically and archaeologically.

The Logic of Economic Defensibility

Half a century ago, the biologist Jerram Brown published a short paper entitled "The Evolution of Diversity in Avian Territorial Systems" (Brown 1964). Brown's immediate goal was to explain why some bird species are strongly territorial, others are not, and some species in fact alternate between territorial and open-access regimes. Further variation exists in the immediate benefits of

controlling a resource; for many species, it is local patches of food that are defended, while for others, nesting sites or roosts are the object. Brown pointed out that controlling the resources in a territory has benefits, but comes at a cost: time and energy (and potentially risk of injury) spent monitoring an area, advertising one's presence, and deterring intruders. His simple but profound argument was that natural selection would only favor defending territories if the benefits of doing so exceeded these costs – if the net benefits (measured in fitness or its correlates) were positive. This principle has since been labeled *economic defensibility*. Brown gave this principle empirical meaning by linking it to the spatiotemporal distribution of resources – specifically, their density and their predictability.

Dense resources are more defensible (are more likely to repay the costs of territorial defense) because the area the territory holder must defend to control access to a given resource is smaller, thus requiring less time and effort to monitor. Predictable resources are more defensible for two reasons: the area that must be defended to encompass them is easier to locate (spatial predictability) and the income from them is higher and more reliable (temporal predictability). Note that this argument does not entail environmental determinism, since the costs and benefits of both territory defense and resource acquisition also depend on the resource consumer's capabilities (e.g., birds can fly, can advertise territory residence with song, and so on); in the human case, consumer capabilities include technology and other culturally variable attributes.

Although dated in its particulars, Brown's simple argument has greatly helped biologists explain the diversity of animal territorial systems, just as his title had promised. It harnessed the logic of natural selection (i.e., the trade-offs involved in gaining some benefit at some cost and their effects on fitness) to ecological variation. The economic defensibility model has proved remarkably durable and has been validated in hundreds of studies of spatial behavior in a wide variety of species (Davies and Houston 1984; Dubois and Giraldeau 2005). Dyson-Hudson and Smith (1978) published the first anthropological application of

the model. That paper employed qualitative assessments of the economic defensibility model in various ethnographic and ethnohistoric contexts to draw three broad conclusions: (1) territorial behavior (exercise of spatial ownership claims, controlling access to resources) is facultative and varies strategically (demonstrating that people are at least as clever and flexible as birds); (2) this strategic behavior corresponds to variation in resource density and predictability across space and over time, as predicted by the economic defensibility model; and (3) within the same social system (even the same household), territorial strategies may be applied to some resources but not to others. The following section expands on these points, citing relevant ethnographic and archaeological data.

Variation in Human Resource Defense

The basic expectations derived from the economic defensibility model are summarized in Table 1 (after Dyson-Hudson and Smith 1978; see also Cashdan 1992). Note that these expectations and their predictors are stated in ordinal terms (e.g., low versus high density, intermediate defensibility); rigorous tests would require precise quantitative measures rarely found in the ethnographic and archaeological data (for a recent effort to estimate such values, plus a formalization of the economic defensibility model, see Baker (2003)). Nevertheless, the qualitative evidence is quite extensive.

Variation Across Space

The economic defensibility model predicts that, if density and predictability are high enough, territorial systems (property rights in land) will be

favorable. There are many cases in which steep gradients in resource density or predictability correlate with marked shifts in land use. For example, over a vast stretch of the Pacific coast of North America, dense and predictably located runs of salmon fostered permanent villages, territorial claims to salmon streams by corporate kin groups (Donald and Mitchell 1994), and chronic warfare (focused not only on control of resource sites but also on seizing property and slaves). Yet a short distance inland, across the coastal ranges in the Columbian Plateau and Subarctic regions, where resources were much lower in density and also generally less predictable, the indigenous societies had traditional land use patterns stressing communal access rights (the exceptions being favored salmon-fishing spots at falls and rapids, which were sometimes owned by kin groups).

Finer-scale variation in land use within ethnolinguistic areas is perhaps even more convincing. The Eskimoan (Yup'ik and Iñupiat) peoples of coastal Alaska had permanent (winter) villages and strongly defended discrete territorial boundaries (Andrews 1994; Burch 1980). Yet when some Iñupiat spread eastward across the Canadian arctic about one millennium ago, the much lower resource density encountered there led to greatly relaxed boundaries approaching open-access land use. Similar variation in territoriality and related aspects of land use are found in the ethnolinguistically homogenous Great Basin. Most of the Great Basin is very arid, resulting in low resource density and predictability. The indigenous Shoshone and Paiute were highly mobile and had few controls over land use. Yet in well-watered areas such as the Owens Valley, relatively dense and predictable resources were associated with decreased mobility and forms of land ownership that were clearly territorial (Steward 1938;

Resource Defense, Table 1 Resource density, predictability, defensibility, and resultant land use (Modified from Dyson-Hudson and Smith 1978)

	Resource density	Resource predictability	Economic defensibility	Predicted land use
A.	Low	Low	Low	High mobility, dispersed population
B.	Low	High	Intermediate	Home range system
C.	High	Low	Intermediate	Mobility, information sharing
D.	High	High	High	Geographically stable territoriality

Thomas 1981). Archaeological analyses of variation in territorial strategies too numerous to cite here detail similar patterns in varied locations worldwide.

Steep gradients in resource density and predictability can have profound implications for broad aspects of political economy. Many scholars have pointed out that stratified social systems have initially arisen in areas with such gradients, such as fertile floodplain valleys surrounded by arid regions and rainforests with patchily distributed potable water resources. The link to economic defensibility can be quite direct: where kin groups or other coalitions are able to control key resource patches, subordinates have few options, and stable levels of exploitation can increase (Boone 1992; Smith et al. 2010). Again, note that this is not environmental determinism: resource density and predictability are in part functions of social and technological variables (e.g., agricultural techniques, labor division, social stratification), and social agency (in seeking or resisting political and economic domination) is central to the process.

Variation Over Time

A theory of spatial behavior that did not allow rapid change over time would be falsified by the historical record. In fact, the economic defensibility principle leads one to expect such change whenever there are sufficient large shifts in resource density or predictability. These shifts can arise from exogenous factors, such as environmental change that alters these parameters for key resources; or it can be generated by endogenous shifts in resource utilization due to technological, demographic, economic, or political variables.

Examples of both exogenously and endogenously driven shifts in defensibility parameters are evident at various temporal scales. Ethnohistoric data on Algonquian peoples in the North American eastern subarctic document a shift from hunting focused on caribou to semi-sedentary settlement patterns focused on trapping of furbearers and foraging for moose and small game (Bishop 1986). The former pattern was characterized by high mobility, extreme flux in

group composition, and open access to resources, the most adaptive configuration for harvesting caribou with indigenous technology, as these preys clump together and move rapidly and unpredictably across the landscape. In contrast, fish, hare, furbearers, and even moose are dispersed and relatively sedentary prey, most efficiently harvested by foragers in small family-based groups who can economically defend hunting territories and coterminous traplines. The shift from the caribou-hunting economy to the fish/hare/moose/trapping economy was a complex process driven by economic factors (particularly the fur trade) as well as technological (steel traps, guns, etc.) and environmental ones (e.g., caribou declines).

On intermediate time scales, the intensification of agriculture is generally associated with higher labor inputs and shortened fallow, which increase both resource density and predictability. Such intensification is also associated with increased formalization of property rights and wealth inheritance (Shenk et al. 2010), thereby institutionalizing resource defense across multiple generations. On an even broader time scale, it has been argued that the dramatic increase in environmental stability (and thus resource predictability) with the transition from Pleistocene to Holocene climates, coupled with suitable local ecological and social conditions, was necessary for agriculture to develop and spread over much of the globe in the last five to ten millennia (Richerson et al. 2001).

Differential Defense Across Resources

There are many cases in which actors (individuals, households, or larger groups) exhibit territorial behavior with some resources but not others. This can be fully consistent with the economic defensibility model: if resource X is dense and predictable enough to be economically defensible, but resource Y is not, the simplest expectation is territorial defense of X but not Y. An example is the pattern of land use and property rights found among many East African cattle herders, where garden plots and livestock are claimed as property by individuals or households, but grazing land is communally owned by the “tribe” (ethnic group).

This is clearly expected from defensibility logic, as good grazing areas are dependent on patchy and highly unpredictable rainfall distribution, whereas gardens are dense and predictable resources due to direct management. Livestock are even denser and predictable to the extent that people control their movements (Dyson-Hudson and Smith 1978). Extension of this argument to pastoralists in other areas has found broad support for economic defensibility predictions (Casimir 1992).

Group-Level Territoriality and Collective Action Problems

The previous section explained how the spatio-temporal scale of a resource is critical to its defensibility. This logic applies to the demographic scale as well. Suppose a resource is indefensible at the individual level because monitoring and defense costs are too high relative to the benefits of resource control. The resource may become defensible if individuals cooperate in monitoring and defense, and the economy of scale lowers per capita cost sufficiently. For example, East African pastoralists generally do not defend grazing land against members of their own “tribe” (ethnolinguistic group) but violently defended it against encroachment by other tribes. Dyson-Hudson and Smith (1978) admit their model does not explicitly treat intergroup conflict of this scale, focusing analysis of territory defense on the household level. The question then is how to secure the cooperation necessary to defend agricultural plots at the household level and grazing land at the ethnic group level. More generally, how and under what circumstances do individuals solve the problem of cooperative resource defense?

A collective action problem (CAP) arises when members of a collective (e.g., a household, village, voluntary association, etc.) must pay costs to produce a collective good – a resource available to all members of the collective (Olson 1965). Some theorists define CAPs more stringently as any case in which increasing the number of cooperators in a

group increases the average group payoff but any given member of the group is always better off defecting no matter the actions of other members (McElreath and Boyd 2007). The structure of the payoffs to collective action matters. For example, if group members benefit from cooperating whatever their social partners do, there is no CAP to solve (Clutton-Brock 2002). If group members can share the benefits or costs of cooperation and the benefit-to-cost ratio is high enough, a stable mixture of cooperators and defectors (or a stable mixed strategy employing both cooperation and defection) is expected to emerge (Doebeli et al. 2004; Maynard Smith 1982). Even if cooperation is mutually beneficial to all, complications may remain if group members must coordinate their cooperative investments (e.g., in organizing territorial monitoring). The linguistic capabilities of humans certainly facilitate complex coordination and communication of social norms (Smith 2010).

In sum, at least two types of CAPs may occur in territory defense: when it is impossible for a group member to defend the territory alone, and when the loss of territory is not costly enough to a single group member to deter a positive fraction of group members from shirking (Boone 1992). Even in fairly small groups, the mechanisms that potentially ensure cooperation in dyads such as direct reciprocity (Axelrod and Hamilton 1981; Trivers 1971) and kinship (Hamilton 1964) are insufficient (Boyd and Richerson 1988). If enforcement (punishment of free riders) is also costly to group members, a second-order collective action problem must be solved.

One class of solutions emphasizes private (individual) gains linked to collective action. Models of indirect reciprocity posit that individual reputations for cooperation become known through observation or gossip and then cooperators can avoid helping defectors even if they will not have the repeated interactions required for direct “tit-for-tat” reciprocity (Leimar and Hammerstein 2001; Panchanathan and Boyd 2003). Linking this to collective action requires that reputations be determined by contributions to collective action and then subsequent dyadic interactions allow cooperators to withhold aid

from defectors (Panchanathan and Boyd 2004); for example, if B knows A avoids contributing to territory defense, B can then withhold aid from A when A is sick or hungry or wants to arrange a marriage for his son.

Alternatively, contributions to collective action can constitute a signal of individual qualities (such as health, fighting ability, social network size and quality, etc.) that are difficult to observe directly (Gintis et al. 2001), and observers can use the signal to make mutually beneficial “side deals” with above-average signalers by allying with or deferring to them in other contexts (Lyle and Smith 2014).

Another class of CAP solutions involves inter-demic group selection, which involves selection among partially isolated and competing groups in a population. Under this framework, selection occurs both within and among groups. Within-group evolution selects against altruism because altruism is by definition costly to a given group member (e.g., those who vigorously monitor and defend group boundaries may suffer increased mortality risk). Selection among groups favors altruistic participation in group resource defense (collective action) because this increases the average payoff, thus the rate at which the group proliferates at the expense of other groups. Because within group variation is usually much greater than variation among groups, selection must be weaker within groups than between them for group selection to work (Boyd and Richerson 2007). Inter-demic group selection may be more likely in cultural species like humans because cultural transmission occurs on one-to-many and many-to-one bases, which, coupled with conformist bias within groups (“When in Rome, do as the Romans”), will decrease variation within groups and increase variation between them (Henrich and Boyd 2001), paving the way for culturally transmitted group-beneficial traits to proliferate at the expense of individuals. There is some empirical support for group selection involving territorial defense. Soltis et al. (1995) found that cultural group selection among warring territorial groups in New Guinea could have favored group-beneficial traits through the

extinction of groups by assimilation, though at a quite slow rate. Mathew and Boyd (2011) analyze ethnographic data on Turkana cattle raiding as reflecting the effects of cultural group selection.

To sum up this section, territoriality occurring in larger groups requires cooperation among the individuals and smaller social units that make up the group. The cooperation requirement introduces possible collective action problems (CAPs). Solutions to such CAPs might involve complex conditional strategies, interactions between genetic and cultural inheritance, selection occurring at multiple levels, or a combination of these. Regardless of mechanisms, as long as groups do find a way to cooperatively defend territories, the basic predictions of economic defensibility models apply.

Conclusions

This article summarizes the evolutionary ecological approach to resource defense known as the economic defensibility model and application of this model to explain variation in human territorial behavior that demonstrates its robust support in light of ethnographic and archaeological research. It highlights the importance of assessing model validity relative to the appropriate spatio-temporal as well as social and demographic scales. In addition, the economic defensibility principle of territoriality models can be applied to a broad range of resource types, including social networks (Chabot-Hanowell and Smith 2013).

Three main conclusions follow. First, ecological approaches to territoriality developed in biology and anthropology provide a flexible and robust framework for analyzing resource defense in a variety of species, including humans. Second, the net benefits of territorial resource defense are a function of variation in resource density and predictability, as specified in the economic defensibility model, as well as the specific capabilities of the competing individuals or groups. Finally, human territoriality involves a complex set of practices that vary within and across societies

and thus requires nuanced understanding and application of evolutionary ecological models.

Definition

The economic problem of having inadequate resources to fully satisfy needs.

Introduction

While the psychology of resource scarcity is a new research area, the universality of resource scarcity has been a foundational assumption in modern economic analysis. Accordingly, limited resources required for satisfying our needs (e.g., labor, capital, and time for production or food for consumption) are always limited, which forces any rational individual to prioritize efficiency concerns (i.e., how to make the best use of resources at hand). This combines with the idea of diminishing marginal utility – another foundational concept in modern economics – to suggest that the economic value of a good, as reflected on its market price, increases with its level of scarcity. Despite its critical role in defining economics as the science of efficient use of scarce resources, however, effects of scarcity on the psychology of decision-making have been ignored until recently. It remains an implicit assumption in modern economic theory that the motivation for efficiency gains is independent of the level of scarcity (Isler 2009). Recent findings on the cognitive aspects of scarcity suggest that this assumption can be misleading (Shah et al. 2015), thereby directly linking the

foundations of economic science with evolutionary psychology.

Literature Review

Isler (2009) provided an early philosophical criticism of the “dominance of scarcity” in mainstream economics, hypothesizing that the formal framework of rational choice misleadingly results in the implicit assumption that humans are always fully motivated to efficiently use scarce resources. This assumption has over the past decade been subjected to serious empirical questioning, which resulted in promising findings that can guide both evolutionary psychology and experimental and behavioral economics towards new directions (Mullainathan and Shafir 2013).

Shah et al. (2015) showed in a series of experiments that low levels of income are associated with increased concern with opportunity costs and with making trade-offs, reflecting a focus on efficiency. The authors also showed value judgments of low-income participants to be less open to the influence of irrelevant contextual cues. Separately, Salerno and Sevilla (2019) found that people perceive scarce foods as having more calories. Together, these results suggest that scarcity increases expected utility for the goods in question and induces people to prioritize efficiency concerns for the task at hand, thereby moving people closer to the ideal of *homo economicus* presumed by rational choice theory.

This attentional focus, however, is also found to come at a high cost. Shah et al. (2012) devised a series of economic experiments for studying the undesirable cognitive effects of scarcity. Participants were assigned to scarce or abundant resource conditions (number of attempts available) in various tasks such as solving puzzles, some of whom were allowed to borrow resources from future rounds at high interest. Among resource-poor but not resource-rich participants, the ability to borrow improved short-term performance at the expense of worsened overall scores. Similarly, Tamm and Zhao (2016) showed

resource scarcity to improve memory of information about the scarce resource, while increasing attentional neglect of unexpected opportunities as well as weakening memory of abundant resources. These results highlight the main cognitive side effect of resource scarcity: increased focus on the current task results in attentional neglect of more distant opportunities through cognitive fatigue.

The finding that scarcity impedes cognitive function has substantial policy relevance, since it implies that poverty can in part be self-fulfilling. For example, Mani et al. (2013) found that Indian farmers experiencing seasonal income fluctuations exhibit improved fluid intelligence and cognitive control after harvest, when incomes are at peak levels. This and similar findings strongly suggest that poverty can breed more poverty through attentional neglect and cognitive impairment of economic decisions.

The link between resource scarcity and cognitive scarcity is likely to be a fundamental part of human psychology. For instance, Huijsmans et al. (2019) found in an fMRI study that the inducement of scarcity vs. abundance mindsets activated different neural networks associated with valuation and goal-directed choice. Given its underlying neurological basis, attentional focus and neglect due to scarcity are likely to shape heterogeneous domains of behavior. For example, Krosch and Amodio (2014) found economic scarcity to enhance biased perception of race, indicating that scarcity increases out-group discrimination. Similarly, scarcity manipulations have been shown to increase selfishness, deceptiveness, and antisocial behavior at the expense of cooperation (Prediger et al. 2014; Roux et al. 2015).

Conclusion

These findings directly link the economic concept of resource scarcity with the dual-process model of cognitive processes. Given that resource scarcity was – although varying in extent – a predominant feature of our evolutionary past and a critical determinant of our evolutionary success, it is perhaps not surprising that resource scarcity has

fundamentally shaped how our minds work. Research on the cognitive effects of resource scarcity is in its infancy, and the study of scarcity's relationship with intuitive cognitive processes promise to shape economics and evolutionary psychology.

Male resource provision plays an important role in parental care and offspring survival; as a consequence it can act as a signal that is important in female mate choice. Male resource provision involves providing material extrinsic investments in the form of food, shelter, and protection and can be signaled through wealth and status.

Introduction

Because human babies require a longer period of parental care compared to other mammals,

parental investment by both sexes can have implications for offspring survival (Hill and Hurtado 1996; Nettle 2008). Since males invest in parental care through extrinsic material investments, through resources in the form of food, shelter, and protection, it pays for women to select mates that have the ability to make these provisions (Symons 1979). Males show off (signal) resources through wealth and status because females have marked preferences for those who do (Buss 1989; Pawlowski and Dunbar 1999). Resources may therefore act as a signal of mate quality that is important in female mate choice.

Resources as a Signal of Parental Investment

We contribute to offspring survival in two ways: one, through passing on our genetic code (good gene quality) and, two, through parental care (good provider quality) (Trivers 1972). Human babies are relatively costly to produce and raise. The increased size of the prenatal brain in humans means that to allow for the large head to pass through the birth canal, birth at 9 months is relatively premature compared to that of other primates (Portmann 1990). This means that human babies are more helpless than other mammals; they are more dependable and require a longer period of parental care. Because of the demands of raising human babies, both female and male parental care contributions (as well as their good gene contributions) are important for offspring survival. Whereas female parental care typically involves biological intrinsic investments, in the form of pregnancy and nursing, male parental care involves the provision of material extrinsic investments, through resources in the form of food, shelter, and protection (Symons 1979). Male status and level of resources therefore can influence offspring survival. Children without a father face greater mortality risks, especially in preindustrial societies without predictable and accessible food production and modern health care (Hill and Hurtado 1996). Even in Western societies with access to government social and health care, the lack of paternal involvement

could have negative impacts on offspring in terms of IQ and social mobility (Nettle 2008). Females therefore who seek males with high resources would gain fitness advantages for doing so, and males who signal resources may be selected over those who do not.

Males' Signal Resources to Attract Mates

Signaling theory highlights underlying attributes that cannot be directly observed, but can be communicated to others through signals (Bliege Bird and Smith 2005). By showing off resources (through wealth and status), males can signal to females their underlying mate quality as a good parental investor. By engaging in conspicuous consumption (driving an expensive car, wearing a designer suit), an individual can indicate their underlying wealth or status and therefore their ability to provide for offspring. Veblen's (1973) theory of "conspicuous consumption" suggests that consumption of luxury goods signals a person's underlying financial quality. Males therefore gain reproductive advantages by "showing off" (signaling) these traits in the presence of a potential female mate. Females gain reproductive advantages by choosing males who display traits that help them to produce and rear better quality offspring. In humans, men competitively show off their quality through status and resources. In restaurants, groups of men leave much better tips for waitresses than groups of women, and men on dates with women leave especially good tips (Miller 2001). Even mobile phones have been shown as a resource status symbol. Lycett and Dunbar (2000) found that in social situations, males tended to be more visual with their mobile phone use; in particular, males tended to show off and play with their mobile phones more as the ratio of males to females increased. They argue that males competitively display their mobile phones as indicators of wealth and status. Showing off resources has real fitness implications; among hunter-gatherer societies, men who regularly provide large animal meat have more sexual partners (Hawkes and Bliege Bird 2002). In more contemporary settings, such as lonely heart

adverts, males, when seeking a mate, will highlight their luxury consumption (cars, houses, holidays) significantly more than females. Pawlowski and Dunbar (1999) compared the lonely heart adverts of 454 males and 445 females (aged 18–59) in a UK newspaper (*The Observer*) in the late 1990s. They found that while women tended to offer signs of fertility (physical attractiveness) and seek resources (cues of wealth and status), males tended to seek physical qualities of fertility and offer resources (through referring to themselves as a house owner and professional or suggesting a lavish lifestyle: holidays abroad and expensive cars). Resources however may be used as a bargaining power to access high-quality mates. Male advertisers who did not mention cues of status/wealth in lonely heart adverts were less demanding of the qualities they sought in the opposite sex (Waynforth and Dunbar 1995). However, when men are primed with feelings of financial wealth, they raise their minimum requirements for a date. Yong and Li (2012) exposed male and female participants to either stacks of paper, a small sum of money, or a large sum of money. After handling large sums of money, men, but not women, raised their minimum requirement for a dating partner, particularly the attractiveness of that date partner. Similarly, Li et al. (2016) tested how feelings of having more or less money influenced long- and short-term mating strategies among Chinese college students. They found when men were primed to feel they had more money, they were less satisfied with their long-term partner's physical attractiveness. This same finding was not found for women.

Females Are Attracted to Signals of Resources in Mates

Women seek men who are good providers and select males who display cues of high social status and wealth. Because of higher reproductive and parental costs (Bateman 1948; Trivers 1972), females are more strongly influenced by non-physical factors than males. For example, Townsend and Levy (1990) found that social status could enhance females' existing perception of

physical attractiveness in prospective mates. Whereas both sexes value physical attractiveness in a potential partner, women value social status more in long-term relationships, across both Western (American) and Eastern (Singaporean) sample populations (Li et al. 2011). In a seminal paper, David Buss (1989) confirms that these sex differences are universal. He found that across 37 cultures, women place greater emphasis on status and wealth, and males place emphasis on sexual fidelity and physical attraction. Even resource potential is valued by women. Through analysis of lonely heart adverts (taken from the "Eye Love" section of the fortnightly UK magazine *Private Eye* between January and June 1991), Greenlees and McGrew (1994) found that women, more than men, sought cues that revealed resource potential (ability to acquire resources in the future) as well as actual resources. Qualities such as intelligence and education signal a male's resource potential and are consequently considered attractive mate qualities by females (Miller 2001). Education can act as a measure of socioeconomic status, because education correlates with personal income and occupational position. For example, Bereczkei and Csanaky (1996) found that Hungarian women preferred males with either the same or higher education than themselves. Women however may make a trade-off between a mate's parental investment and genetic benefits. When women have less need for men's resources, for example, when they possess their own resources to take care of their children, they place greater emphasis on physical attractiveness of a mate over good financial prospects (Moore et al. 2006). The desire for resources in a mate can depend on the economic environment in which women are selecting mates. McGraw (2002) analyzed lonely heart adverts published in the United States in 1999 and found that as the costs of living increased, the desire for a mate with the capacity for better financial resources increased also. Women were adopting conditional mating strategies depending on specific environmental factors to optimize their reproductive opportunities. Anderson and Klofstad (2012) sampled 2944 Internet dating profiles in the United States, and found that

women in high-cost living areas increased their desire for mates with resources. However, when women's own resource status was taken into account, no significant relationship in local resource pressure and resource seeking was found. Nevertheless, even in environments that have faced dramatic cultural change, women more than men value resources in potential mates. Souza et al. (2016) compared the Brazilian mate preference scale answers from 1984 (as presented in Buss' 1989 Culture Mate selection project) and 2014. They found that even through industrial and economic transformations, males still place greater emphasis on signals of fertility (health, youth), whereas women place greater emphasis on "good earning capacity" and "good financial prospects" – highlighting social status, education, intelligence, ambition, and industriousness as important mate qualities.

Females Are Attracted to Signals of Willingness to Share Resources

Although females may be attracted to males who signal resources, the extent to which males invest their resources in offspring should also be of concern for women. Signals of disposition toward parental investment as well as level of resources should be attractive traits for women. For example, it would not be an advantage for a woman to mate with a man with high resources but who spent these resources on other women and offspring. Kruger et al. (2003) found that women's expectations of having a short-term versus long-term relationship depended on whether males displayed qualities of "dads" or "cads." They found that "dads" were preferred as long-term relationships, but "cads" were preferred as short-term relationships. They argue that, due to risk of mate defection, women discount males with "cad" features for long-term relationships, even if they also display suitable resources. In contrast, men who signal compassion, kindness, and romantic qualities (or "dads") were valued by females as long-term partners. By showing willingness to share

resources, males can signal good "dad" qualities. This may explain why males, more than females, are more likely to show off financial generosity by donating more money to charity if they are knowingly observed by an attractive member of the opposite sex (Iredale et al. 2008). It may also explain why females, when selecting for long-term relationships, have marked preferences toward males who cooperate and share their resources (Farrelly 2013). So important is this signal of willingness to share resources that males compete to show off financial generosity (Roberts 1998). For example, males have been seen to sequentially increase their public good donations when observed by a female in both Western and non-Western populations (Tognetti et al. 2012; Van Vugt and Iredale 2012).

Conclusion

Male parental investment through resource provision can have significant implications for offspring survival (Hill and Hurtado 1996; Nettle 2008). Females therefore have marked preference for males who display resources, and males show off resources (through wealth and status) to attract a mate (Buss 1989). Female preferences for mates with resources however can depend on their own financial wealth and the wealth of the environment (Anderson and Klofstad 2012; Moore et al. 2006). Similarly, males may vary their mating demands depending on their own wealth and status (Waynforth and Dunbar 1995; Yong and Li 2012). Although, for females, there are fitness benefits for mating with males with good resources, willingness to share these resources may be a more important signal of mate quality than resource acquisition alone (Kruger et al. 2003).

Definition

A source of supply, support, wealth, or revenue; a natural feature or phenomenon that could increase human brain size, efficiency, or health.

Introduction

Throughout the process of evolution, human development has been tied to the need to adapt to our environments and compete for resources. Traits such as bipedalism, manual dexterity, and vocalization are among the many characteristics that have allowed for humans to proliferate (Jabr and Quanta Magazine [n.d.](#)). Of all the adaptations that make our species unique, none are more important than the human brain. The brain is one of the largest, most sophisticated and vital organs of the body, and all of its astounding complexity is the product of millions of years of evolution (“Evolution of the Human Brain” [2019](#)). Its success and development have been very much connected to the resources it has been exposed to. Although identifying and describing each resource that has been vital to brain evolution and development would be too expansive, for this article we will seek to identify some of the main resources complicit in human brain evolution.

Resources and Experience

The development of the brain is based on a collaboration of nature with nurture. However, the percentage inherited vs. the percentage created by experience is still unknown (Siegler et al. [2017](#)). And while the importance of genetic predisposition cannot be discounted, experience and exposure are paramount for development. This process of experience can be described as being experience-expectant or experience-dependent (Prado and Dewey [2014](#)).

Experience-expectant refers to the process in which brain development occurs secondary to experiences that are expected to occur (Prado and Dewey [2014](#)). An example would be “visual

input through the optic nerve for normal development of the visual cortex (Prado and Dewey [2014](#)).” Experience-dependent refers to the ongoing process of brain development resulting from an individual’s unique experiences (Prado and Dewey [2014](#)). Woollett reported that London taxi drivers were shown to have increased volume in the hippocampus secondary to the experience driving the city streets. The role of the environment and nurture on development is therefore a consequence of expected milestones during sensitive periods as well as a continuing process in which our everyday occurrences modify our anatomy and physiology.

Resources in Development

The first environment all humans experience is in utero. There, the fetus is dependent upon the mother not only for access to nutrients but also for maintaining an environment that can facilitate proper development. These factors include proper prenatal nutrition facilitated by the mother and minimal exposure to toxins, infections, or external elements. On the other hand, some agents can negatively impact brain development if mothers are exposed to them at critical junctures during pregnancy. Teratogens are agents that can provoke or increase the risk of a baby being born with a birth defect. These agents could be street drugs, alcohol, tobacco, chemicals, and some viruses and bacteria.

Severe acute malnutrition, chronic undernutrition, iron deficiency, and iodine deficiency can significantly impair brain development. Therefore, resources such as proper nutrition of the expectant mother may have to include supplementation to ensure nutrients are being attained. Prado and Dewey ([2014](#)) stated that research has demonstrated that nutritional supplementation can have influence to brain development and that *recovery is plausible* if the nutrients are made available while the developmental process is still occurring. Development can also be inhibited in certain situations, such as when we are going through a significant amount of stress in our daily life. This means that the brain has very

sophisticated adaptive functions where, depending on the experience the person is going through, it can either regenerate more neurons or decrease neurogenesis according to the current external situation (Siegler et al. 2017).

Once the baby is born, the environment becomes much more expansive. This continues to increase as we grow and begin to ambulate independently. Because babies can neither read nor fully speak until more advanced stages of development, they usually learn from observing others, connecting with their parents and caregivers, and exploring the environment. One of the most important factors for a healthy brain development is nurturing and taking care of the child (“Early Brain Development” n.d). Proper care and exposure of children to different experiences, from when they are born until the end of their childhood, ensures that the child’s brain will develop appropriately; therefore, positive and negative experiences will affect the child’s development and can portray enduring effects. Exposing the child to stressful or traumatic situations could possibly exhibit long-lasting negative effects in the brain of the child, whereas other constructive activities such as reading and playing can instead stimulate their brain growth (Allen 2015).

As soon as children are born, they are ready to learn; however, they depend on their family and caregivers to help them develop the competencies that will allow them to become independent and manage a healthy life in their future. The level of development that the child’s brain reaches is strongly linked to their experiences with the world that they encounter while growing up. Children exhibit better learning abilities when they grow under conditions of social support and emotional well-being, which are derived from constructive relationships held inside and outside their homes. Parents and other caregivers can sustain the children’s healthy brain development by incentivizing positive learning. The most efficient way to achieve this is by speaking and playing with the kids, exposing them to books, and telling them stories that would help the children develop their curiosity, self-confidence, and moral understandings.

Moreover, the experiences children go through when they are growing up can directly affect their future mental health and brain development. Mental health affects how people think, feel, and act; therefore, growing up in a safe and healthy environment would shape our brains to be able to cope with different life challenges. Two common recommendations for child mental health and brain development are to “use it or lose it” and to perform regular exercise. Stimulating our nerve cells by reading, learning, and thinking improves mental fitness and even leads to the development of new brain cells. However, if we stop stimulating our brain, we could lose some crucial abilities that help us overcome daily challenges while keeping a healthy lifestyle (Pendick 2012). On the other hand, doing regular exercise helps the stimulation of blood flow through our body, therefore, assisting our brain to obtain the nutrients and oxygen we need to maintain a good brain functioning. Additionally, exercise can improve mood and activates the release of hormones and chemical substances that enhance brain health.

Nutrition as a Lifelong Resource for Brain Development

A shortage of nutrients in utero and during early stages of life could lead to impairments in the functions of the brain, negative effects in brain development, and cognitive deficits through and after the developmental process (Cusick and Georgieff 2016). Through the development of the brain, the effects of nutritional deficiency are determined by the nutrient’s specific metabolic physiology (what processes are impacted during brain development and whether the insufficiency takes place during a critical or sensitive period). Even though the brain undergoes plasticity throughout our lifetime, and it is able to recover from a nutrition deficiency, during development, there are critical periods where parts of the brain have greater nutritional needs (“What to Feed Your Child to Support Healthy Brain Development” 2019). Deficiency in crucial nutrients over a critical period results in long-lasting negative effects (Cusick and Georgieff 2016).

Children who undergo malnourishment suffer the risk of not being able to reach the maximum potential of development in crucial aptitudes such as cognition, socioemotional abilities, and motor skills. Studies have shown that providing supplements to pregnant mothers and children throughout the first few years of life has provided long-lasting positive effects in the child's cognition as they develop (Prado and Dewey 2014). On the other hand, research suggests that breastfeeding may improve cognitive development due to the plethora of nutrients, hormones, and important growth factors that are found in the breast milk. Additionally, the mere act of breastfeeding strengthens the mother-infant relationship, which is considered crucial for healthy brain development (Prado and Dewey 2014).

Brain-Derived Neurotrophic Factor (BDNF)

BDNF is a protein encoded by specific genes that facilitates important functions in neural development, survival, and regeneration (Marosi and Mattson 2019). It is defined as a potent small protein that stimulates new brain cell's production and reinforces the existing ones. Therefore, it is scientifically proven that increased levels of BDNF upsurge the ability of faster learning, more efficient memory, slower aging, and a quicker rewiring of the brain (Marosi and Mattson 2019). Additionally, it is also known that BDNF participates in boosting the **plasticity** of the brain – the power of the brain to adapt to positive or negative changes at any age (Kolb et al. n.d.). During a stressful situation when the brain cells suffer damage, plasticity takes place by increasing the flexibility in the neural pathways instead of shutting down the connections in the brain (Marosi and Mattson 2019).

Moreover, BDNF is a very important protein in sustaining homeostasis. It regulates patterns of feeding and physical activity and stimulates glucose transport to strengthen cellular bioenergy while protecting neurons against possible damage and illnesses (Marosi and Mattson 2019). Our

body releases the protein fibronectin type-III domain (FNDC5), which contains proteins that increases BDNF, by doing exercise (Rasmussen et al. 2009), and, simultaneously, releases BDNF throughout the deep stages of sleep. On the contrary, two main blockers of this protein are stress and sugar. As stress remarkably inhibits BDNF, it has also been proven that the intake of sugar (especially fructose) tends to curb BDNF production in rats (Stranahan, et al. 2008) and links to a cognitive decline in humans (Barnes and Joyner 2012). Mutations of the human BDNF gene are usually associated with cognitive and behavioral disturbances (Narayanan et al. n.d.).

Research indicates that BDNF is fundamental to postnatal survival due to the fact that in experiments where mice have lacked this protein, they exhibit critical deficiencies in the development of the peripheral nervous system and mild defects in the development of the central nervous system (Murray and Holmes 2011). Lastly, exercising positively affects BDNF even during homeostatic disturbances such as stress or disruptions in energy metabolism. Research studies indicate that exercise in reasonable intensity and frequency has been shown to upsurge the BDNF expression after each exercise session in humans (Liu and Nusslock 2018).

Conclusion

Throughout human evolution, we can conclude that the brain has endured a diverse set of changes. Continued research is important to understand these ancestral evolutionary changes, such as genetic abnormalities and modifications and to also find new resources that help us improve our performance and skills throughout our lives. It is important to emphasize how the initial periods of the children's lives are vital for their further development. The brain of a child produces more than a million neural connections each second from the time they are born until the age of three ("Brain Development" n.d.); therefore, proper stimulation and enhancement are crucial for their development. As it was previously discussed in this

article, throughout evolution, the development of the brain has been influenced by many factors, including the children's interactions, experiences, and environment where they are raised. Factors such as exercise and deep sleep can aid in the release of BDNF, a resource that enhances the development of a healthy brain, but a greater benefit can be achieved when these factors are combined with a proper nutrition.

Definition

A group of cognitive processes that prevent participants from providing accurate responses or cause them to alter their behavior in a given situation.

Introduction

Response biases are a group of cognitive processes that prevent participants from providing honest or accurate responses to questions or cause them to alter their behavior from what they would normally do in a given situation. These response biases act as a source of error in data collection, sometimes obfuscating data slightly, sometimes completely invalidating them. As such, it is incredibly important to account for response biases as much as possible when constructing measures for studies and during the actual collection of data.

Response biases can stem from several sources. Sometimes participants intentionally alter their responses in order to deceive the researcher in some way. This can occur when participants wish to alter how they appear to the researcher, such as when a participant responds in such a way as to appear “better” than they truly are. In other circumstances, participants may actively deceive the researcher in order to hide information, such as illegal activities. Other times something about the study itself may influence the participants’ behavior without their being aware of it. This can occur when questions in a survey are unclear or confusing, making it difficult for respondents to provide accurate answers despite a desire to do so. Lastly, bias can result from a lack of attention on the part of the participant. This is especially common when participants are not adequately compensated for their time and when participation in research is strongly encouraged (as is the case in most undergraduate introductory psychology courses). This also occurs when participants become fatigued during long or demanding studies. Addition of attention-check items can mitigate this effect. Examples of common response biases are discussed below. Regardless of their source, however, all response biases lessen the ability of the researcher to confidently interpret the data and can sometimes render the data useless.

Types of Common Response Biases

Social desirability. Social desirability is the tendency for an individual to deny traits and behaviors deemed unacceptable by society and to claim traits and behaviors deemed acceptable by society, casting themselves in a favorable light (Nederhof 1985). Participants answering in socially desirable ways can change the mean levels to the response (Podsakoff et al. 2003), as well as conceal the relationships between variables (Ganster et al. 1983). Social desirability can be managed by the researcher using techniques to measure and control for the effects of social desirability or by using methods to reduce or prevent social desirability (Nederhof 1985).

Acquiescence bias. Acquiescence bias (i.e., yea-saying) is the tendency for participants to agree with statements. This tendency can cause spurious relationships between variables, capturing an artifactual relationship rather than the true relationship between variables (Podsakoff et al. 2003). Acquiescence is positively correlated with age and negatively correlated with both education and income worldwide (Meisenberg and Williams 2008). Acquiescence bias can be managed by including reverse-coded items so that affirmative responses do not indicate the same response for each item. The opposite of acquiescence bias, nay-saying, is also managed by reverse-coding items.

Extreme response style and “fence-sitting.” Extreme response style is the tendency for participants to use the end-points of a scale. This tendency may be due to a desire to appear more sincere or answer with more conviction (Cheung and Rensvold 2000). Alternatively, the opposite of an extreme response style, sometimes known as fence-sitting, is the tendency to select the midpoints of a scale. This may be due to participants attempting to appear modest or nonjudgmental (Cheung and Rensvold 2000). Extreme response style can be managed by including a greater number of points on a scale (e.g., going from a 5-point scale to a 10-point or continuous scale). Both extreme response styles and fence-sitting can be managed by utilizing other methods of questionnaires, such as binary choice or open-ended questions.

Conclusion

While this entry only discusses a subset of the possible response biases, it illustrates some of the possible artifacts which can be present in a researcher’s data, and how to account for and prevent their effects. For additional information on possible data artifacts, see Podsakoff et al. (2003).

Responsibility for Child Suffering

Definition

The moral debate surrounding the ethics of reproducing and responsibility for any subsequent suffering that the individual experiences.

Introduction

Responsibility for child suffering is the foundation to the anti-natalist claim that it is morally wrong to create new life. In line with anti-natalism, the ultimate responsibility for any suffering a person endures in their life is attributable to their parents, as a nonexistent person cannot consent to be born and as all individuals can be expected to experience some degree of suffering. On the other hand, pronatalists argue that holding parents responsible for all of their child's suffering typically ignores an extensive chain of more direct and immediate possible causes of suffering rendering the ultimate responsibility with the parents as a reduction to absurdity.

Responsibility for Harm

Although it could be argued that causing a person harm *with* their consent is not necessarily immoral, few would argue that causing a person harm *without* their consent is immoral. The cause – and thus responsibility – for harm is therefore central to the ethical debate on reproduction. Pronatalists argue that parents can't be held responsible for the suffering of their children as long as they did not cause it directly. The causal chain of responsibility ends once an adequate source of fault is found. This may not be the immediate source of the harm, but in all but the most extreme cases (e.g., known and certain genetic disorders that cause great suffering), the chain of responsibility is regressed to insignificance before reaching the individuals' very conception. For example, it may not be fair to solely blame a soldier for killing or maiming an enemy soldier in a war between their respective countries, but (assuming the soldiers were acting on orders) the countries, governments, or those involved in starting the war can more appropriately be blamed before the enemy soldiers' parents for conceiving him or her in the first place. Similarly, responsibility does not necessarily need to be placed with anyone at all. For example, parents are arguably not responsible for the suffering if their child gets cancer, assuming they did

not intentionally cause the cancer and did not know that their child would get cancer before he or she was born. In this way, pronatalists would argue that, when suffering is not inevitable and not predictable before birth, responsibility can be placed elsewhere. However, anti-natalists would argue that at least some suffering is inevitable and predictable from before birth and therefore responsibility can and should be placed with the parents.

Anti-natalism asserts that we can and should be held accountable for not taking all the possibilities into account when we make them possible and thus parents are responsible for creating the *possibility* and *inevitability* of suffering where none before existed. People can be accountable for negligence, which is making a choice to do a thing knowing that a bad outcome is possible and not taking all the necessary precautions. From this view, procreation would only be morally justified if there was some method for acquiring consent from the person to be born, and, as this is impossible, procreation is thus immoral (Licon 2012). That is, if a person imposes life without consent and without control of the outcome, they are responsible for the suffering and death that life will experience.

According to philosopher David Benatar (2006), the infliction of harm is morally wrong and to be avoided, and therefore, as procreation always entails the infliction of harm to some extent, procreation is always morally wrong. Benatar's argument is based on the following premises:

1. The presence of pain is bad.
2. The presence of pleasure is good.
3. The absence of pain is good, even if that good is not enjoyed by anyone.
4. The absence of pleasure is only bad if there is somebody for whom this absence is a deprivation.

From these premises, it is argued that if someone exists, there is the presence of pain and the presence of pleasure, whereas if that person had not come into existence, the pain is avoided which is good and the absence of pleasure is not bad (i.e.,

neutral) as the individual does not exist to be deprived of it. For Benatar, the harm that coming into existence creates is avoidable and pointless, and therefore, as it is always good to avoid harm whenever possible, it is always good not to come into existence.

Conclusion

In summary, from the combination of the predictability and inevitability of harm and the lack of prior consent from the individual who will experience this harm, anti-natalists argue that the responsibility for any and all suffering that a child experiences is with the individuals who brought them into existence. From this stance, biological parents are ultimately responsible for all the harm their child experiences, regardless of any more immediate or direct specific sources of harm, as it would have been avoided if the child had never been born in the first place.

Retina, The

Definition

The retina is the tissue that undertakes the initial steps of image formation in the visual system, being the tissue within the eye formed of photo-receptors and other cells.

Introduction

In vertebrates, the focus herein, the retina lines the inside of the globe of the eye, whereas in invertebrates the eye takes on many forms and the retina is often exposed more directly to the environment.

The Vertebrate Retina

By way of analogy, the vertebrate eye is often described as being “camera-like” in that it has lenses and apertures that focus light onto a thin detection layer. In this analogy, the retina is the *film* of the analog camera – the component that is sensitive to light – and the signals thus generated are interpreted by the brain. Research over many decades has revealed that this analogy is very limited: the retina does much more than detect light but instead is a complex network of neurons that processes these signals to simultaneously compute and encode information about a stimulus’ shape, color, movement, intensity and contrast, among several other characters. Thus, if we are to portray the eye as analogous to a camera, the

retina is more akin to a contemporary smart phone: detecting light towards image formation is a required and impressive function of this tissue or device, but merely the beginning of a complex conversion of immense information that is translated, computed, refined, and transmitted to produce remarkable outcomes. Despite ocular structures having long been celebrated for their elegance and efficiency (Darwin described this an “inimitable contrivance” in a chapter titled “Organs of Extreme Perfection”) (Darwin 1858), they are indeed typically still underestimated in how marvelous they are.

Akin to film in an analog camera, the retina is a sensitive and precise component whose operation is critical to vision, and disruptions to the retina structure or function are causal of many types of visual impairment and blindness.

For many researchers, the retina is considered “an accessible part of the brain,” e.g., as asserted by John Dowling (2012). Unambiguously, the retina is part of the central nervous system, formed during embryonic development as a lateral out-pocketing of the forebrain. Like the brain, the retina is made up of a complex suite of neurons and supporting cells (such as vasculature and microglia, radial glia forming a blood retina barrier akin to the blood brain barrier). The retina is experimentally “accessible” compared to other vertebrate CNS tissues in many synergistic ways, including being readily examined for health by instruments of ophthalmology and optometry. The morphology of the retina lends itself to study due to its regularly layered structure created by consistent connectivity of identifiable neuron subclasses (Fig. 1). Functional measures are relatively tractable, because the retina is comparatively easy to record from, e.g., via electroretinogram, and easy to stimulate because light as a stimulus can be precisely controlled in both its quality and quantity. Experimentally, the retina is accessible to treatment delivery via intraocular injection into the globe of the eye. These sum to retina being highly amenable to comparative sensory ecology and fundamental neuroscience, as well as to being an attractive target for development of emerging CNS treatment modalities designed to ameliorate neurodegeneration (such

as gene therapy, stem cell therapy, and neural prostheses) because outcomes can be elegantly and powerfully measured in longitudinal study designs and safety of the interventions can be carefully monitored using the ophthalmologist’s toolkit.

The retina tissue is formed from diverse cells including many subtypes of photoreceptors, support cells, and neurons (Fig. 1). Photoreceptors and downstream neurons are distributed in three layers and make up the “neural retina,” whereas the broader term “retina” often is used to describe both the neural retina and the retinal pigmented epithelium (RPE). The RPE lines the back of the eye and interdigitates its processes with the rod and cone photoreceptors. The RPE plays several roles, including impeding off-axis light from reaching the photoreceptors, and supporting photoreceptor metabolism by phagocytosing photoreceptor outer segments and recycling visual pigments. Such support roles are critical because photoreceptors are highly metabolically active cells, producing much protein to support absorption and transduction of light.

The photoreceptors in the retina are the cells that perform phototransduction, i.e., they convert light stimuli into biochemical and electrical signals that eventually are computed in the brain to manifest as vision. The vertebrate retina is considered to be “duplex” because vision is accomplished by two classes of photoreceptors: the rods and the cones. A third class of photoreceptor, the intrinsically photosensitive ganglion cell, does not participate in vision but instead communicates about light levels to regulate the size of the pupil and to entrain circadian rhythms, i.e., simply these ipRGCs help to tune the master biological clock that adjusts day/night biological rhythms. The ipRGCs are rhabdomeric photoreceptors and have distinct physiology as compared to rods and cones that are ciliary photoreceptors, in that ipRGCs express distinct opsin (melanopsin) and phototransduction machinery (Fain et al. 2010). Rhabdomeric photoreceptors underpin vision in many most invertebrate species; thus, ipRGCs share similarities with invertebrate visual receptors. The last common ancestor of vertebrates and invertebrates perhaps then had both rhabdomeric

Retina, The, Fig. 1 Schematic of typical vertebrate retina. The vertebrate neural retina has several distinct layers, beginning closest to the eye's vitreous is the ganglion cell layer (GCL) – this layer is closest to the pupil and faces the arrival of environmental light. Behind this are the inner and outer nuclear layers (INL and ONL), and photoreceptor outer segments (OS) form a distinct compartment. Photoreceptor outer segments interdigitate into the retinal pigmented epithelium (RPE), a darkly pigmented layer of support cells. Photoreceptors underpinning the first steps of vision are rods and cones. Vertebrates typically have four types of cones maximally sensitive to different wavelengths of light: the example here is cones maximally

sensitive to blue and ultraviolet (UV) light (both with a single cone morphology) and a double-cone morphology maximally sensitive to red and green light (wherein two independent cone photoreceptors are fused). Mammals have less complexity in their complement of cones (see text). The cones synapse onto cells of the INL, wherein photoreceptor outputs are compared and calculated by horizontal cells and amacrine cells. Bipolar cells transmit these signals to the RGCs. The RGC axons form bundles running along the inner surface of the eye and coalesce into the optic nerve that transmits retinal outputs to the brain. Not represented in this schematic is the diversity of glia and vasculature that is also critical to retinal function

and ciliary photoreceptors, and this state is observed in extant annelids (Fain et al. 2010). We will not consider ipRGCs further but go on to consider rod and cone photoreceptors as the cellular instigators of vertebrate vision.

Rod and cone photoreceptors have much in common, expressing opsin in the apical end of the cell called the outer segment that is engulfed by the RPE. These photoreceptors are highly polarized cells, with inner segments dense with mitochondria to feed their high metabolism, below which are the nucleus and active perinuclear protein production and trafficking machinery, and extending synapses basal direction, towards the center of the eye where they connect to downstream neurons (see Fig. 1). The photoreceptor outer segment elaborates much

bilipid membrane to maximize the abundance of opsin. Opsins are proteins that begin the process of vision – they absorb photons of light and, via changing their shape and signaling to other proteins, convert the light signal into electrochemical nerve pulses.

Rod and cone photoreceptors differ in their functions and are named for differences in their namesake morphology: Rods have outer segments that are shaped like rods, whereas the outer segments of cones typically are more conical (Fig. 1). Vertebrate vision in very low light environments begins with rods. Rods are very sensitive and famous for being able to respond experimentally to a single photon of light. Rods are quenched by moderate light levels, e.g., during crepuscular times of day (dawn or dusk), such that they are

of most utility under light levels provided by starlight or moon light. Rod photoreceptors typically express an opsin that maximally absorbs photons of 500 nm wavelength (green light).

Cone photoreceptors are active in moderate light levels and brighter, and are responsible for high-acuity vision. Cone photoreceptors mediate color vision by having multiple spectral subtypes – e.g., humans have populations of cones maximally sensitive to red, green, or blue light. Thus, each cone typically expresses a single opsin type and responds maximally to certain wavelengths of light. Color perception begins in the retina when the outputs of the various cone photoreceptors are compared. Vertebrates typically have four cone spectral subtypes that are maximally sensitive to ultraviolet, blue, green, and red photons. Mammals lost much of this array of photoreceptor complexity during the nocturnal bottleneck, a phase of early mammalian evolution wherein

adaptation to nocturnal lifestyle was perhaps enabled by changes in the retinal photoreceptors and led to evolution of thermoregulation (Kim et al. 2016). Thus mammals, including those that have subsequently evolved diurnal (daytime active) habits, often have only two cone photoreceptor types. Primates including humans typically have duplicated long-wavelength cone opsin gene and thus have trichromatic vision.

The proportion and density of cones varies among different species. An extreme example is in some primates, where cones are dense in the macula and fovea, wherein few rods are present. In many vertebrates, a similar condensation of cones such as a “visual streak” or “area centralis” is observed and presumably allows that area of the retina to maximize its resolution of shapes and colors. Cone photoreceptors of most vertebrates, e.g., fishes, are arranged in a crystalline lattice (Allison et al. 2010) where cones of different

Retina, The, Fig. 2 Cone photoreceptors are typically patterned into crystalline mosaics. Though lost during evolution of tetrapods, most vertebrates have their cone photoreceptors organized into elaborate array of reiterated spacing and neighbor relationships. The view schematized here is an oblique angle relative to Fig. 1 and presents a “row mosaic” typical of many fish including zebrafish,

though other variations on this pattern are also common. Cones maximally sensitive to blue or ultraviolet (UV) light have a single cone morphology and alternate to form rows. Double cones are a fusion of cones maximally sensitive to red or green light and establish elaborate rows between the single cones

identities are regularly positioned in an elaborate spatial array (Fig. 2).

Cone photoreceptors are also arbiters of sensory modalities that not generally part of the human experience. For example, cones are the arbiters of polarized light vision in vertebrates, and this ability has various functions in detecting predators and prey, detecting celestial cues for navigation, and for social communication (Kamermans and Hawryshyn 2011). Cones also are responsible for light-dependent magnetoreception in vertebrates (Niessner et al. 2011), which is thought to play various roles especially including long-distance migrations.

Conclusion

Thus the retina, enabling the first steps in vision (Rodieck 1998), is remarkable in its ability to disambiguate various environmental energy signals, including not only specialization for magnetic fields and polarization of light but also simultaneously allowing complex perceptions of the environment by encoding movement, intensity, shape, flicker, and colors.

Richard Dawkins on Constraints on Natural Selection

Introduction

Richard Dawkins presents a nuanced take on optimality in his seminal work *The Extended Phenotype*. Dawkins's central argument is that optimality is *not* attainable in nature because of constraints on the process of natural selection. His discussion focuses on six key constraints: time lags, historical

constraints, trade-offs (which he calls constraints of costs and materials), constraints due to available genetic variation, imperfection due to selection operating at different levels, and constraints due to environmental unpredictability.

Together, these six constraints on optimality offer a deeper understanding of how natural selection works and the kinds of outcomes it produces. They also help lay to rest the erroneous view that evolutionists endorse a Panglossian, pan-adaptationist view in which every aspect of animals' bodies and brains is optimally designed. No credible evolutionist thinks this. Instead, it is widely understood that natural selection builds suboptimal adaptations because of the following key constraints.

Time Lags

Evolution by natural selection is a gradual, step-by-step process. As a consequence, organisms are adapted to *past* circumstances, not present circumstances. If it so happens that the environment has not changed much, then organisms may be well adapted to their current environment. But if the environment they inhabit has changed, organisms can exhibit maladaptive behaviors simply because environmental change has taken place faster than the slow, cumulative process of evolution by natural selection.

For example, humans are adapted to a time in which food was scarce. As such, our species has evolved taste preferences for calorie-dense foods, fat, and sugar (Buss 2015). In the calorie- and nutrient-scarce environments in which we evolved, these preferences were adaptive. By contrast, in modern environments with an overabundance of fast food, these evolved taste preferences lead to obesity, type II diabetes, and cardiovascular disease. They are no longer adaptive because of the discrepancy between the environment in which we evolved and the one we currently inhabit (Nesse and Williams 1994). Stated differently, the environment has changed too fast for selection to keep up: time lags have rendered our adaptive taste preferences maladaptive in modern environments.

Historical Constraints

History provides a second key constraint on the power of natural selection. When an engineer sets out to build something, she can always start over if something goes wrong in the process. By contrast, natural selection is constrained by millions of years of history. Once a certain body plan or nervous system is in place, certain areas of evolutionary “design space” are closed off for that lineage, and others are rendered less “evolvable” (Dennett 1996). In other words, the phylogenetic background of a species affects what it is capable of evolving next: history constrains evolution.

Consider the case of how jet engines superseded propeller engines (Dawkins 1999). Designers of the first jet engine had a blank canvas from which to construct prototypes. This meant that they were not forced to stick with any initial mistakes or missteps they made – they were free to start from scratch if needed. Moreover, in the case of humanly engineered machines, there is no need for each new step in the process to be an improvement on its predecessor: our foresight enables us to add or change parts that have no immediate effect, but that will eventually improve the machine’s functioning when the design is complete.

Natural selection has neither of these luxuries. It cannot start from scratch; it can only build upon what is already there – and every single intermediate step must function better than its predecessor. These constraints limit the power of natural selection to produce optimally designed mechanisms. The consequence is suboptimal designs such as the vertebrate eye, which has a blind spot and appears to be installed backward (Dawkins 1999). Such a design is suboptimal by engineering standards – but there are limits on natural selection that do not exist in engineering.

Trade-offs

Every adaptation comes with a cost, and this makes trade-offs inevitable. For example, gazelles under predation pressure from wolves may evolve

longer legs, enabling them to run faster and increase their likelihood of escape. But longer leg bones are more brittle and more likely to break. The gazelle thus faces a cost either way: more robust bones but diminished capacity to flee or enhanced capacity to flee but more vulnerable bones. Some trade-offs are simply unavoidable.

The blind Mexican cavefish (*Astyanax mexicanus*) illustrates the same point. Over millions of years, this fish has lost its sight. One hypothesis for how this happened involves trade-offs: the Mexican cavefish may have lost its eyes because vision requires energy-hungry neurons, and in a pitch-black cave it is a waste of metabolic resources to build and maintain a visual system. In such an environment, those physiological resources can be more profitably channeled toward something else – cell repair, immune function, or a stronger tailfin, for example.

The key point is that every adaptation imposes a cost. These costs lead to unavoidable trade-offs – and if the trade-off is truly unavoidable, then it is impossible to optimize the traits being traded off against one another. Because of this, trade-offs lead inexorably to suboptimal designs.

Available Genetic Variation

Natural selection cannot make new genes arise out of thin air; it can only work with whatever genetic material happens to be available in a population at a given time. As a result, the availability of genetic variation is a key constraint on natural selection. To put it differently, it is impossible for natural selection to produce an adaptation – let alone an optimally designed one – if the relevant genes are simply not present in the population.

It is difficult to exaggerate the importance of this point. The selection pressure for a particular trait may be exceedingly strong, but this will not matter at all if there is no genetic variation underlying that trait. No matter what other factors are in place, the trait in question will not evolve unless there happens to be genetic variation for it in the population. An analogous constraint in human engineering would be the following: it is

impossible to build something – no matter how badly we need it – if we simply do not have the raw materials with which to build it.

Artificial selection on cattle illustrates this point. Researchers carried out experiments in an attempt to produce more heifer (female) calves rather than bull calves, as only heifers produce milk. However, it turned out that the genetic variation required for this outcome (producing more female offspring) did not exist, so the experimenters were unable to produce the desired sex ratio (Dawkins 1999). The key point is this: if the relevant genetic variation does not exist, the trait will not evolve – no matter how long natural selection operates and how strong the selection pressure is. Natural selection is unavoidably constrained by the raw material that happens to be available in the population at the time.

Imperfections at One Level Due to Selection at Another Level

Optimality in nature is also constrained by the fact that selection at one level can lead to maladaptive effects at another level. Dawkins describes this in the following way: “selection at the level of the gene can give rise to apparent imperfections at the level of the individual” (Dawkins 1999).

Heterozygous advantage provides an illustrative example. In such cases, a gene may be positively selected because of its beneficial effects when in a heterozygous state. But when in a homozygous state, the effects of such a gene are harmful. For example, the allele for sickle-cell anemia has been selected for because it is protective against malaria in a heterozygous state. However, if a person inherits *two* copies of this allele, he or she will develop sickle-cell anemia, which can be fatal (Allison 1954). It is thus possible for selection at the genic level to have detrimental effects on an organism’s health. And because it is impossible to optimize two conflicting levels (genic and individual) simultaneously, suboptimal outcomes are unavoidable.

Mistakes Due to Environmental Unpredictability

Dawkins’s final constraint is that of environmental unpredictability. Animals may be exceedingly well adapted to their environments, but since some environmental events are inherently unpredictable, mistakes and missteps are inevitable.

For example, a bird may be well adapted to fly in conditions that are, on average, favorable to flight. But it would not be surprising for the mechanism of flight to fail in a severe hurricane. Unpredictable catastrophes can kill even the most well-adapted organisms. As Dawkins puts it, “it will usually be impossible to cater to every conceivable contingency of detail, and any given animal will therefore frequently be observed to make ‘mistakes’, which can be fatal” (Dawkins 1999).

Stated differently, organisms are adapted, on average, to the statistical conditions of their environments. But no matter how well designed an animal’s flight or vision or bipedalism might be, some environmental events are anomalous and unpredictable. Natural selection is constrained by this unpredictability and cannot build biological mechanisms that are somehow immune to random environmental accidents. Environmental unpredictability thus acts as a sixth key constraint on the power of natural selection.

Further Constraints: Antagonistic Pleiotropy and the Conflict Between Survival and Reproduction

These six limits on the power of natural selection to produce optimally designed mechanisms are not exhaustive, but space considerations prohibit us from offering a comprehensive account of all the constraints on natural selection. We briefly mention two others here: (a) conflicts between survival and reproduction and (b) antagonistic pleiotropy.

Survival and reproduction often come into conflict in nature. Because differential *reproduction*, not survival, is the bottom line of evolution, when they do conflict, reproduction inevitably trumps survival (Alcock 2009; Dawkins 1976;

Williams 1966). The peacock's tail illustrates this well. It is a burden to survival: cumbersome, metabolically expensive, and a hindrance when it comes to escaping from predators. But peacock genes build these tails anyway because peahens are attracted to them – such is the power of sexual selection. The key point regarding the conflict between survival and reproduction is this: because it is impossible to simultaneously optimize two conflicting outcomes (survival and reproduction), suboptimal outcomes are inevitable. And because differential reproductive success – not survival – is the currency of evolution by natural selection, design for reproduction takes precedence. This often leads to suboptimal design for survival (see, e.g., Al-Shawaf et al. 2015).

Antagonistic pleiotropy – a phenomenon in which a single gene may have conflicting effects (Nesse and Williams 1994; Williams 1957) – provides another constraint on optimality. For example, some genes have beneficial effects in early adulthood but detrimental effects in later adulthood. This is the case with genes for testosterone production, as testosterone enhances male reproductive success in early adulthood but increases susceptibility to a wide variety of diseases in later years (Trivers 1985; Williams and Nesse 1991). And because selection is more powerful earlier in the life span and weaker later in the life span (after reproduction has already occurred; Nesse and Williams 1994; Williams 1957), it will favor genes that help the organism early in the life span even if they hurt it later on. In this way, antagonistic pleiotropy – combined with the waning strength of selection across the life span – constitutes another key driver of suboptimal design in nature.

Conclusion

Richard Dawkins's seminal account of the limits of natural selection focused on six key constraints: time lags, historical constraints, constraints due to available genetic variation, trade-offs, imperfection due to selection operating at different levels, and constraints due to environmental unpredictability. To these six key constraints, we

briefly added two more: antagonistic pleiotropy and the conflict between survival and reproduction.

One more theoretical point bears mentioning. Natural selection should not be understood as an optimizing process at all – instead, it is a “meliorizing” process (Dawkins 1999). That is, natural selection does not produce the best design possible by engineering standards – rather, it produces designs that are *better*, on average, than the other available designs in the population at the time.

This definition of natural selection, together with the eight constraints discussed above, explains why natural selection cannot produce optimally designed mechanisms in nature.

We hope this entry helps elucidate the nature of these constraints on natural selection, why they exist, and the important role Dawkins has played in highlighting them. We also hope this entry underscores the erroneousness of the oft-repeated criticism that evolutionary scientists think adaptations are optimally designed. They are not, of course – for all the above reasons.

Richard Lewontin and Stephen Jay Gould

John Alcock

School of Life Sciences, Arizona State University, Tempe, AZ, USA

Stephen Jay Gould was (he died in 2002) a celebrated evolutionist and writer, someone who was called a Living Legend by the US Library of Congress in honor of his many literary achievements. Richard Lewontin, a fellow Harvard Professor when Gould was alive, is known for his pioneering research into the genetics of variation within populations as demonstrated by gel electrophoresis, a technique that shows just how much hereditary variation there is in the populations of living things.

Both men deeply opposed the work of sociobiologists and evolutionary psychologists, two groups of researchers who use the adaptationist approach, which involves employing natural selection theory as the basis for investigations into the possible adaptive value of behavior. One expression of their resistance to this approach came in an extremely influential paper published in the Proceedings of the Royal Society B (Gould and Lewontin 1979) on the supposed failures of adaptationism. This paper has been cited nearly

3000 times according to the Web of Science. In their piece, Gould and Lewontin argued that the “adaptationist program” involved faith in the ability of natural selection to produce adaptations without consideration for other likely influences on evolution. Further, adaptationists were, according to Gould and Lewontin, prone to produce “adaptive stories,” generally of a speculative nature, that they accepted on the basis of plausibility alone, which is to say without the rigorous testing against alternative explanations that is the hallmark of a truly scientific approach (see The Just-So Story, also by Alcock). The ignored alternatives included those that focused on the origin rather than the current utility of a trait of interest as well as the power of such things as genetic drift in addition to natural selection in affecting the course of evolution.

In their paper, they introduced the concept of a spandrel, namely, a significant structural component of a building or body that was later co-opted for some other additional purpose in the course of building an edifice or developing a body as in the decorations on the supports of arches in cathedrals. The argument here was that the decorations on spandrels are not adaptations per se, but instead are mere by-products of an object that originated for other reasons altogether.

Gould elaborated on his opposition to the “adaptationist program” in many of his broadly read monthly contributions to *Natural History* magazine, 300 in all, thereby enlarging the effect of his views on the utility of natural selection theory (as well as its modern addendum, kin selection theory) as the foundation for research into possible adaptations. He was a productive writer with frequent pieces in the *New York Review of Books* as well, where he once wrote (Gould 1997) that evolutionary psychology and its adherents were fatuous, foolish, and pathetic, among other things.

The assault by Gould (and Lewontin) on evolutionary psychology and the like failed ultimately although the intensity of the attack disconcerted some adaptationists in some fields as seen in the reluctance of sociobiologists to employ the word “sociobiology.” But natural selection theory (in conjunction with its modern

modifications) is without doubt the most important tool ever devised for sociobiological and psychological researchers interested in the evolution of the complex behavioral traits of living things, including humans. The record of exploration of the adaptive value of these traits by natural selectionists is breath-taking in its scope as can be seen in any textbook on animal behavior or evolutionary psychology (Alcock 2013; Buss 2015; Gaulin and McBurney 2003).

Among the many counters to Gould and Lewontin's arguments were responses written by other evolutionary biologists, like Borgia (1994), who pointed out that among other things the adaptationist program involves the use of natural selection theory to produce hypotheses about the possible adaptive value of a trait of interest so that one or more of these hypotheses might be *tested*, a point that Gould never acknowledged. The scientific literature is filled with examples of tested hypotheses on the adaptive value of this or that characteristic. So *contra* Gould and Lewontin, adaptationists do not settle for plausibility as the criterion for acceptance of a hypothesis. Scientific journals do not either, which is why selectionists must and do test their ideas before submitting them to the scrutiny of a journal and its reviewers.

Moreover, Gould and Lewontin blurred the difference between adaptationist research on the possible adaptive significance of traits and studies of the origin and evolution of these traits. In reality, there are two different kinds of evolutionary studies, one that focuses on adaptation (i.e., current and past reproductive or genetic value of the attribute) and another that focuses on the historical sequence of changes that have occurred during the evolution of a characteristic. These are related areas of research but they are different in that one (adaptationism) relies heavily on Darwinian natural selection as the underlying hypothetical cause of the trait in question, while the other focuses on the role of preceding changes in shaping the attribute in question.

Furthermore, evolutionary studies, whether on the possible adaptive value of a trait or on the history of modifications of the trait over time, differ profoundly from research into the

proximate causes of the trait of interest. So when Gould and Lewontin state that adaptationists are at fault for not analyzing the role of development in the production of a trait, they are confounding the proximate (immediate developmental) and ultimate (evolutionary) causes of the character under investigation. This error is a fundamental one that has long been known to cause many misunderstandings and unnecessary arguments (Mayr 1961). The developmental biologist and the geneticist have interesting and valuable roles to play in understanding how a trait comes into being but they are under no obligation to expand their studies to include the possible adaptive value of the trait. Likewise, the adaptationist is not obliged to consider the proximate foundation of a trait if he or she is more interested in testing why the trait has been shaped and maintained by natural or kin selection.

Although Gould and Lewontin tried to argue that Darwin was a pluralist who even-handedly dealt with all manner of causes in his efforts to explain how and why a trait came to be the way it was, a pluralist of this sort he was not (Queller 1995). Darwin's *On the Origin of Species* is almost entirely about the role of natural selection in producing the adaptations of living things. Indeed, Darwin was the first adaptationist who realized how powerful selection could be in shaping the attributes of all animals, plants, bacteria, and fungi. Here is what he actually said about the nature of adaptation with all three quotes coming from his book on orchid adaptations (Darwin 1862), which he wrote in the years immediately after publishing *On the Origin of Species*:

When this or that part has been spoken of as adapted for some special purpose, it must not be supposed that it was originally always formed for this sole purpose. The regular course of events seems to be, that a part which originally served for one purpose, becomes adapted by slow changes for widely different purposes. (p. 282.)

Although an organ may not have been originally formed for some special purpose, if it now serves for this end, we are justified in saying that it is specially adapted for it. (p. 283.)

On the same principle, if a man were to make a machine for some special purpose, but were to use old wheels, springs, and pulleys, only slightly

altered, the whole machine, with all its parts, might be said to be specially contrived for its present purpose. Thus throughout nature almost every part of each living being has probably served, in a slightly modified condition, for diverse purposes... (pp. 283–284)

I would not quote Darwin on these matters except that Gould and Lewontin claim, irresponsibly, that the author of *On the Origin of Species* was in their corner, when he most definitely was not.

So why were Gould and Lewontin so eager to downplay the role of Darwinian natural selection in the evolution of adaptations? Here I rely on Trivers (2015), who in his review of the two biologists, notes that both were ideologues of the Marxist variety, believers in the ability of cultural pressures to shape human behavior in ways that made all behavioral possibilities equally likely. Lewontin (1976) wrote, “As working scientists in the field of evolutionary genetics and ecology, we have been attempting with some success to guide our own research by a conscious application of Marxist philosophy.” Ironically for persons who were eager to attribute ideological bias to their opponents, both Gould and Lewontin permitted their own political views to profoundly affect their conclusions about adaptationism (Borgia 1994; Queller 1995; Trivers 2015). Their ideological biases also caused them to argue against what they portrayed (inaccurately) as the genetic determinism of adaptationists. In fact, Gould and Lewontin tried to equate adaptationism (an evolutionary approach) with genetic determinism (a proximate claim about the nature of development) in order to assert that the adaptationist approach is obviously wrong, since human behavior is indisputably variable, a point known to all.

Why does it matter? After all, Gould died long ago in 2002. Since his demise, sociobiology (broadly defined to include behavioral ecology) and evolutionary psychology have flourished. Durant and Ellis (2003) found that the number of papers in evolutionary psychology had increased from 4 to 231 per 4-year blocks beginning in 1985 and ending in 2000. The field has expanded even more vigorously since 2000 (Webster & Jonason, 2009). If we examine the frequency of the use of

“evolutionary psychology” as a keyword in 2211 papers covered by the Web of Science starting in 1973, 1424 or 64% have occurred in the last decade (beginning in January 2007). So a great many researchers have in recent years come to make use of the adaptationist program despite the complaints of Gould and Lewontin.

However many of us realize that Gould is still accepted as an evolutionary authority by those who are not evolutionary researchers themselves. As Borgia (1994) noted, evolutionary biologists may have a strongly negative view of Gould and his anti-adaptationist stance, but non-evolutionary types are far more accepting. Non-evolutionary commentators often repeat the points made by Gould and Lewontin as if they were novel and had never been rebutted by scientists who disagreed with these arguments (e.g., Gottlieb 2012; Slater 2013). Indeed, many philosophers of science, social scientists, and economists, even non-evolutionary psychologists, believe that evolutionary theory is completely irrelevant for their studies of human behavior. Gould and Lewontin provided a reason for these individuals to ignore natural selection theory and to the extent that they influence the thinking of their students and the general public, the evolutionists among us need to keep trying to explain why the adaptationist program is not only viable but essential if we are to fully understand human behavior.

This effort is all the more necessary to the extent that creationists continue to have a strong influence in the United States where over 40% of respondents accept the creationist account of the origins of human beings (Gallup Poll 2014). Gould’s critique of adaptationism, despite his many anti-creationist activities, was used by creationists in their ongoing efforts to attack evolutionary thinking. Creationists need to be countered to the extent possible by showing why Gould (and Lewontin) were mistaken in their anti-adaptationism.

There are therefore several reasons why Gould and Lewontin’s spandrels paper deserves continuing rebuttals from evolutionary biologists and psychologists who are aware that adaptationism is the foundation for the success of behavioral

ecology and evolutionary psychology in making sense of animal behavior.

Richard Wrangham, Ruth B. Moore Professor of Biological Anthropology at Harvard University, founder of Kibale Chimpanzee Project, and Co-founder of the Kasiisi Project.

Introduction

Richard Wrangham was born 1948 in Britain and earned his PhD at Cambridge University in 1975 and is a Ruth B. Moore Professor of Biological Anthropology at Harvard University. Dr. Wrangham researches primate ecology and human nutrition and social behaviors. He has authored or co-authored many books such as *Science and Conservation in African Forests: The Benefits of Longterm Research*, *Demonic Males: apes and the Origins of Human Violence*, and *Catching Fire: How Cooking Made Us Human*. Dr. Wrangham is a board member, co-founder, and co-director of the Kasiisi Project. Dr. Wrangham is also the founder of the Kibale Chimpanzee Project.

Kasiisi Project and Kibale Chimpanzee Project

The Kasiisi Project, located in Uganda, was founded in 1997 in order to aid in educating in tangent with the Kibale National Park. The Kasiisi Project serves as a link between locals and the Kibale Chimpanzee Project (Kasiisi Project 2017). The Kibale Chimpanzee Project, founded to study the behavior, ecology, and physiology of wild chimpanzees in 1987 (Kibale Chimpanzee Project 2017), has been dedicated to the survival, welfare, and understanding of chimpanzees

(kibalechimpanzees 2013). Some recent research by Dr. Wrangham done with the Kibale Chimpanzee Project involves social customs, reproduction, hormones, and disease in chimpanzees (The Kibale Chimpanzee Project 2017).

Recent Research

Listing some of Dr. Wrangham's work, he has completed research on social constructs within chimpanzee groups that has examined grooming behaviors and learning, foraging, and hunting calls. Chimpanzees' have unique grooming styles per group in and out; how these styles developed were unknown. Wrangham et al. found that individuals keep their mother's style and are not influenced by other chimpanzees, impacting community traditions for generations (Wrangham et al. 2016). Foraging in chimpanzees is primarily done by females; however their ability to forage is affected by their group, particularly how many males are in the group and if they have children. In a recent article, Thompson et al. determine that having many males in a group has long-term costs associated with reproduction via negative effect on C-peptide levels and foraging capabilities (Thompson et al. 2014). Hunting initiative of chimpanzees has also been examined, finding that groups of male chimpanzees often have constant initiators that spur on the group to hunt, including non-common hunting participants within the group. After the removal or death of the common initiators fewer hunts are enacted (Gilby et al. 2015).

Books

Dr. Wrangham has extended some of his work to humans; two primary examples being his books *Demonic Males* and *Catching Fire*. In *Demonic Males*, Dr. Wrangham examines the great apes in his travels in Africa, detailing violent behaviors in both humans and nonhuman great apes. In his book, he looks at the common ancestry of great apes to today discussing the differences in how humans have developed opposed to the other

great apes (Wrangham & Peterson, *Demonic Males: Apes and the Origins of Human Violence*, Wrangham and Peterson 1996). In his book *Catching Fire*, Dr. Wrangham covers the possibility that humans evolved to what humans are today because of cooking. In that cooking made digesting and eating more efficient allowing the brain to develop further (Wrangham 2009).

Conclusion

Dr. Richard Wrangham studies a variety of subjects in relation to chimpanzees and humans. He is a distinguished author and publicist, co-founder and co-director of the Kasiisi Project, and the founder of the Kibale Chimpanzee Project. His recent work has examined behaviors in chimpanzees such as grooming behaviors and learning, foraging, hunting calls, and more. He has extended some of his work to humans, one example being his book *Demonic Males* comparing common ancestry and violent behaviors. In another book, *Catching Fire*, he examines how humans may have gained the ability to evolve the brain to how the human brain is today.

Definitions

Risk factors are factors that increase the chances of an untoward event.

Introduction

Understanding of health and illness remains incomplete without the consideration of risk factors. As risk factors are present much before the outcome, their understanding will help in promoting health and preventing development of illness. Outcome of the risk factors in the context of health refers to illness, disease, or disorder. For a given health-related adverse outcome in different individuals, the profile of risk factors in those individuals is not the same. This is because multiple risk factors interact among each other, as well as with the protective factors, in a highly complex manner to cause disease. The strength of association of risk factors with the index individual is also very important for understanding a particular outcome. For example, positive family history of schizophrenia increases the risk of development of schizophrenia in an individual; however, the risk of development of schizophrenia in that individual depends upon the number of family members affected with schizophrenia and the degree of genetic relationship (first-degree, second-degree, or third-degree blood relative) with the affected individual(s). Similarly, if a twin is affected, the risk of development of schizophrenia in the other twin sibling depends upon whether they are monozygotic or dizygotic twins.

Therefore, within a category of risk factors (e.g., family history of an illness), many risk-determining variables exist. The complex permutation and combination of multiple such variables within multiple risk factor categories combine to influence a particular health outcome.

Types of Risk Factors

Risk factors can be broadly divided into two subtypes (modifiable risk factors and non-modifiable risk factors). Modifiable risk factors are those which can be prevented, altered, and manipulated. Non-modifiable risk factors cannot be altered or manipulated. For example, stress is a risk factor for depression, which is modifiable; however, female sex, which is also a risk factor for depression, is non-modifiable. The risk factors that

cannot be modified are also called as fixed risk factors. The modifiable risk factors are also known as variable risk factors. Risk factors can take the form of biological, psychological, as well as sociocultural variables, according to their constituents. For example, in the causation of depression, “positive family history of depression among the first degree relative” can be a biological risk factor, whereas “poor coping skills” is a psychological risk factor and “isolation,” and “cultural taboo” can be sociocultural risk factors (Bernard and Krupat 1994).

Evolution of Risk Factors

Association between risk factors and disease are well-established. The nature of risk, however, changes with time. In modern society, there are several emerging risk factors that significantly influence global health, including mental health. The major emerging risk factors currently are pollution, relational difficulties, exposure to radiations, exposure to toxins (pesticides), maladaptive lifestyles, technology, war and terrorism, and epigenetic changes. Over several decades, there has been a significant change in the intensity and extent of exposure to the above risk factors, which is likely to affect the risk of physical as well as mental illnesses. Similarly, stress has also evolved significantly over time, which is a potential risk factor for ill health. The causes of stress, nature of stress, intensity, and frequency of exposure to stress have changed over time. These evolving risk factors affect health significantly.

Globally five major health-related risk factors have been identified, which attributes to mortality by increasing the risks of chronic diseases (World Health Organization 2009). These risk factors are:

1. Hypertension
2. Diabetes
3. Overweight and obesity
4. Tobacco use
5. Lack of physical activity

Similarly, several risk factors that contribute to global burden of diseases are being underweight,

unsafe sexual activity, unsafe (unhygienic) water, and alcohol use, of which the first three factors are commonly reported in underdeveloped and developing countries (World Health Organization 2009).

Distribution of Risk Factors

Risk factors vary across different socioeconomic strata. Evidence suggests that people from low socioeconomic strata often suffer from nutritional deprivation in comparison to people from higher socioeconomic status (James et al. 1997). The risk factors also change with sociodemographic variables like age, gender, and occupation. Old age, being female, and having a stressful job can be considered as risk factors of depression. Certain religion (e.g., Islam) can be instrumental in protecting from suicide as it is considered as a sin in various religious texts. Similarly, poor social support can be a risk factor for onset and maintenance of psychiatric illnesses. Geographic and climatic conditions also influence health; hence they can also be considered as potential risk factors. Stress-related disorders like acute stress reaction and post-traumatic stress disorder are common in regions where war, terrorism, natural calamities, and disasters are common. Similarly, seasonal affective disorder is commonly reported among people living far away from the equator region.

Risk Factors: Clinical Implications

Every illness has certain risk factors. During evaluation of clients in therapeutic settings, the risk factors that might have contributed to the development of the illness as well as progression of illness, or which might impede treatment, need to be identified. Identification of risk factors help in understanding the etiopathogenesis of an illness. It contributes to the explanatory model of illness. Identifying the modifiable risk factors and targeting their alteration are the mainstay treatment goals for most noncommunicable as well as infectious diseases. Risk factors segregate the population into two halves on the basis of its

degree of association with an outcome: one segment of the population who are at high risk of developing a health ailment and the other segment being at a relatively lower risk (Offord and Kraemer 2000). Minimizing the risk factors in order to restore the well-being of the individual is an important goal of treatment.

Risk Factors: Implications in Prevention

Identification of risk factors for health conditions helps in prevention of development or progression of a disorder. For example, unprotected sex is a potential risk factor for transmission of HIV infection. Understanding this risk factor helps in prevention of transmission of HIV infection. There are two models (predictive model and explanatory model) which operate on the basis of understanding of the risk factors in prevention programs (Fig. 1). The predictive model is built on the basis of various risk factors attributing to a health condition and often target the population at risk. The explanatory model targets to risk factors (causal factors), rather than the population (Schooling and Jones 2018). For example, air pollution causes respiratory illness; the predictive model will target the population at risk of respiratory illness (those with asthma or other chronic obstructive pulmonary diseases), whereas the explanatory model will emphasize on control of pollution.

Risk Factors: Research Implications

Various research designs have been implemented in the study of risk factors. Longitudinal studies usually evaluate the temporal association of risk factor (s), with development of disease and removal of risk factor to examine the alteration in the course of disease (Burt 2001). Cohort studies follow groups of a population over a period of time to examine the adverse outcome among the population group exposed to a risk factor in comparison to a population group not exposed to the risk factor. Similarly, retrospective studies also examine the association of risk factor(s) with a disease/disorder by evaluating the population from outcome back to cause. The

Risk Factors,

Fig. 1 Targeting risk factors in therapeutic interventions

population who developed a disease are examined for previous exposure to risk factors in the past and are sometimes compared to healthy individuals exposed to those risk factor(s).

Risk Factors: Statistical Relevance

Risk is always a probability that predicts the occurrence of an event (Burt 2001). Probability estimation of an event (e.g., disease) in epidemiology is also known as risk estimation. Estimation of risk factors provides insight for planning the therapeutic interventions. Risk factors are considered as a clinical correlate of health whereby their prevalence increases the probability of an adverse health outcome (Offord and Kraemer 2000).

Statistical techniques are useful in estimation of risk for a health condition among the broader population (Schooling and Jones 2018). Studies predict the risk, as well as attempt to establish a biological or psychological link with the etiological factors of a health condition. Significance in a statistical test depends upon the sample size. Estimating the risk factor in a larger sample may show some statistical significance; however, it always does not establish a significant association (Offord and Kraemer 2000). Hence, the nature of risk factor and outcome need to be evaluated before interpreting the statistical findings.

Conclusion

Understanding risk factors fosters a better understanding of health and illness. Risk factors play a pivotal role in the etiopathogenesis of illness and limiting the risk factors help in restoration of health. Given the growing emphasis on prevention of illness and promotion of health, studying and remediating risk factors will help in achieving greater population health.

The Risk of a Lifetime: How, When, and Why Procreation May Be Permissible is a book written by Rivka Weinberg, originally published in 2016 by Oxford University Press. This book discusses procreative ethics and how a contractualist approach can be applied in the context of procreative ethics.

Introduction

Rivka Weinberg is Professor of Philosophy at Scripps College, Claremont (located in California, USA), who received her Ph.D. from the University of Michigan. She is a philosopher and bioethicist who specializes in ethical and metaphysical concerns regarding birth and death (Oxford University Press 2018). She is the author of the book *The Risk of a Lifetime: How, When, and Why Procreation May Be Permissible* (Weinberg 2016), which discusses procreative ethics generally and the application of a contractualist approach (i.e., the view that morality is based on a contract or agreement; see also, e.g., Baumard and Sheskin 2015) to the study of procreative ethics.

The Risk of a Lifetime

In *The Risk of a Lifetime: How, When, and Why Procreation May Be Permissible*, Rivka Weinberg (2016) discusses the importance of carefully considering procreation. She begins with an analysis of the justifiable motivation behind procreation and argues that humans are ultimately individually responsible for the risks we take with our gametes and for the offspring that may develop. Weinberg contends that procreation may be permissible if it is done respectfully and when the child's chances of thriving and living a prosperous, full life are high. Moreover, she asserts that the view that procreation is never permissible because life results in suffering and is imposed on people without their consent is flawed. However, she nonetheless concedes that procreation is a risk from welfare and moral perspectives, even when it occurs under permissible conditions.

In order to assess whether or not procreation is permissible, Weinberg argues that contractualist principles should be applied. Contractualism broadly refers to the view that morality is based on a contract or agreement. Within this view, any act "is wrong if its performance under the circumstances would be disallowed by any set of principles for the general regulation of behaviour that no one could reasonably reject as a basis for informed, unforced, general agreement" (Scanlon 1998, p. 153). In other words, an act is moral when it conveys equal advantage to all involved members of a group. Contractualist principles can be imposed, Weinberg (2016) argues, to fairly take into account both the interests of the prospective parents in procreating and the interests future generations have in prospering in life.

Conclusion

In her book *The Risk of a Lifetime: How, When, and Why Procreation May Be Permissible*, Rivka Weinberg (2016) maintains that life is a risk rather than a gift, but that the risk can be permissible under the right circumstances. She outlines conditions under which she believes procreation is permissible and in so doing takes a middle

position in the debate, arguing against both the view that procreation is never (or almost never) permissible and the view that it is always (or almost always) permissible.

Risk of Conception

Definition

The day-specific probability that a single act of intercourse will result in conception.

Introduction

Conception risk refers to the probability that a single act of unprotected coitus will result in conception. A woman's conception risk varies as a function of life's historical, contextual, and cyclical factors, all of which are accompanied by different hormonal milieus that modulate conception risk (Motta-Mena and Puts 2017). Researchers have drawn on evolutionary theory to posit that women's mating psychology may change in relation to conception risk in adaptive ways. Further, women may adjust their attitudes and behaviors toward men and other women – and be perceived differently by other men and women – as a function of conception risk. Here, we briefly review work suggesting that mating psychology, intrasexual competition, and perceptions by men and other women vary with conception risk.

Although conception risk changes across the 6-day “fertile window” of the ovulatory cycle, peaking approximately the day prior to ovulation (Wilcox et al. 1995), many studies in evolutionary psychology do not treat conception risk as a continuous variable and instead dichotomize it as either nonzero (during the late follicular phase) or zero (during all other cycle phases). Cycle phase and conception risk are frequently assessed through the use of urinary luteinizing hormone (LH) test kits, self-reports of menses dates, or hormone values, with hormonal (including LH) methods being more precise (Gangestad et al. 2016).

Mating Psychology

Women's self-reported desire for sexual behavior rises throughout the follicular phase, peaks around ovulation, and falls during the luteal and menstrual phases (reviewed in Motta-Mena and Puts 2017), and is likely influenced by concentrations of estradiol and progesterone (Roney and Simmons 2013). Increases in general sexual desire concomitant with increases in conception risk may serve as the mechanism by which energy and effort are concentrated on reproductive

behavior, when reproduction is most likely or when the benefit–cost ratio of engaging in sexual behavior is high (Roney and Simmons 2013). Increases in the desire for uncommitted sex or extra-pair sex specifically may also track conception risk, perhaps functioning to recruit genetic benefits for offspring when conception is possible (Thornhill and Gangestad 2008).

Shifts in women's mate preferences as a function of conception risk are comparably less robust. Whereas some meta-analyses suggest that women express heightened preferences for partners with putative markers of genetic quality, such as facial symmetry, vocal masculinity, and behavioral dominance, when fertile (Gildersleeve et al. 2014); others do not (Wood et al. 2014). Moreover, recent large, within-subjects studies have failed to find support for the predicted patterns of association between changes in women's ovarian hormone levels and their preferences for masculine characteristics (e.g., Jones et al. 2018). As such, additional work using large samples and confirmed ovulatory cycle phase or hormonal measures is necessary to detect where shifts in women's mate preferences exist and, if they do, their magnitude.

Intrasexual Competition

Intrasexual competition may increase during periods of heightened conception risk, with observational and lab-based studies suggesting differences in women's clothing and make-up use across the ovulatory cycle. Testosterone is the primary endocrine mediator of changes in self-reported competitiveness, suggesting that increases in intrasexual competition around ovulation may be driven by mid-cycle peaks in testosterone. Levels of intrasexual competition may be predicted not just by a woman's own conception risk, but by the conception risk of same-sex rivals. For example, when partnered women were exposed to photographs of other women taken during ovulatory and non-ovulatory cycle phases, women consistently reported intentions to socially avoid women in the ovulatory (but not non-ovulatory) phase, and only when

their own partners were highly desirable (Krems et al. 2016).

Perceptions

Studies examining participant ratings of women's voices, odors, faces, and bodies generally suggest that heightened conception risk is accompanied by subtle but perceptible cues. For example, increases in progesterone across laboratory sessions (indicating decreases in conception risk) negatively predicted women's facial and vocal attractiveness to both men and other women (Puts et al. 2013). Hormone-driven changes in phenotypes such as complexion, skin color, and facial expression (reviewed in Motta-Mena and Puts 2017) are likely the more proximate causes of differences in perceived attractiveness across the ovulatory cycle. It is possible that such changes function to increase women's attractiveness when they are most fertile, perhaps especially to long-term mates, who might most easily detect such subtle intraindividual changes. Alternatively, changes in observable cues may reflect imperfect suppression of ovulatory cues tied to fluctuating hormones, coupled with strong selection on competitors and potential mates to detect these cues.

Conclusion

Relative to the pronounced genital swellings observed in many other primate species around estrus, physical changes that track conception risk in women are subtle, though likely perceptible by potential mates and same-sex competitors. Cyclic changes in women's mating psychology may function to adaptively allocate mating effort in relation to expected costs and benefits. Future work should continue to draw upon evolutionary theory to identify in which psychological and behavioral domains cyclic shifts may be reliably observed. Such work, and work on shifts concomitant with conception risk more generally, will significantly benefit from a sustained methodological emphasis on

large samples, within-subjects designs, and hormone-confirmed cycle phase.

Definition

Filicide is defined as the deliberate act of a parent, stepparent, or parental figure killing their own child. Subcategories of filicide include neonaticide, when the child is killed within the first 24 h of its life by his or her parents, and infant homicide, sometimes infanticide, although in some countries, infanticide only applies to the mother and the term infanticide has medicolegal implications.

Introduction

Filicide is a phenomenon with many causes and characteristics that are often difficult to isolate. This article looks at the variation of the risk of filicide with parent age: how much the age of the parent influences the likelihood of filicide.

Although a large body of literature exists on filicide, not much of the research focuses on the risk variation with age, as it is often mentioned, but the element of risk variation is not studied. Therefore, most statements in this article regarding risk variation are made based on inferences from the literature, unless stated otherwise.

Many classification systems have been created in an attempt to organize filicide, depending on the perpetrator's gender and the type of crime that is committed. Resnick was the first to attempt to classify filicide with five categories: altruistic filicide, acutely psychotic filicide, unwanted child filicide, accidental filicide, and spouse revenge filicide (1969). However, many other classification systems have been created in addition to Resnick's, for example, Bourget and Bradford (1990), which includes paternal filicide as a separate category. Unfortunately, many of the categories within the different classification systems overlap. In this article, the most commonly recurring categories will be used to organize the information, which are as follows: altruistic filicide, filicide due to mental illness, unwanted child filicide, accidental/fatal abuse filicide, retaliation/spouse revenge filicide, and other/unknown. One section will also cover risk variation with parent age for infanticide and neonaticide.

Altruistic Filicide

A large majority of cases of filicide fall under the category of altruistic filicide (49 % of cases when reviewed by Resnick 1969). This type of crime is generally caused by the parent killing the child because they believe it to be in the best interest of the child. The parent either believes the world is too cruel to leave the child in after their own death or they believe they will relieve the suffering of the child, for example, if the child had a disability (whether real or imagined by the parent) that the parent cannot tolerate. No specific research has covered parent age in altruistic filicide, but it is safe to assume that the parent might either be much younger or much older, as they might be incapable of safely taking care of the child or lack the necessary support (Daly and Wilson 2013).

Filicide Due to Mental Illness

Mental illness is one of the main causes of filicide. A sample of 6144 people convicted of child homicide showed that fathers were more likely than mothers to be convicted of filicide (male to female ratio 2:1) but mental illness was more common in mothers (66 % vs. 27 %) (Flynn et al. 2013). The study found the average age of the perpetrator to be 27 years old, with 16 % of them being teenagers when the child was born. Lewis and Bunce showed that psychotic women who had committed filicide were generally older than non-psychotic women (2003).

Unwanted Child Filicide

This can be compared to infanticide and neonaticide (which will be covered later in the article) as the child is regarded as a hindrance. This category also includes parents who benefit from the death of the child, for example, by receiving insurance money or marrying a partner who does not want stepchildren. Because of its similarity to neonaticides and infanticides, we can infer that the risk of unwanted child filicide would increase the younger the parent is.

Accidental/Fatal Abuse Filicide

Accidental filicide and fatal abuse filicide is often linked with mental illness. One study suggested that the younger the parent, the higher the risk of fatal abuse or accidental filicide, as the parent does not know how to take care of the child or has other children to take care of (Connelly and Straus 1992).

Retaliation/Spouse Revenge Filicide

This is the rarest type of filicide (Friedman and Resnick 2007). Because this depends on the relationship between the parents, the parents' age is not very relevant and it's therefore possible to assume the risk of filicide does not vary much with the parent's age.

Infanticide and Neonaticide

The classification systems of filicide do not generally include infanticide and neonaticide. The risk of filicide varies between filicide, infanticide, and neonaticide. The average parent age for filicide is 29 years old, on the other hand, the average parent age for infanticide is 23.8 years old (Brewster et al. 1998), and the average parent age for neonaticide is 21.2 years old. We can therefore conclude that from this study the younger the parent, the higher the risk for neonaticide, infanticide, and filicide, respectively. This study, specifically looking at risk factors for infant homicide in the United States, found that one of the strongest predictive factors of filicide was a maternal age of 15 years (relative risk, 6.8 as compared with 25 or more years) (Overpeck et al. 1998).

Conclusion

The research on risk variation of filicide with parent age remains a topic with limited research. The current literature seems to suggest a higher risk of filicide for young parents, generally

mothers who are in difficult and deprived circumstances. However, Flynn, Shaw, and Abel argue that because young mothers have a lack of education, economic opportunities, and marriage stability, they are at a greater risk of hurting themselves than they are of hurting their infants (2013). Therefore, more research on the parent age in filicide needs to be done in order have a clearer picture of the risks associated with it.

Introduction

The study of risk propensity has a long and rich history of inquiry in various disciplines such as biology, economics, and psychology (see Mishra 2014 for a recent overview). In the evolutionary psychological sciences, currently, the main debates mostly revolve around the role that life-history variables and the early living environment have on risk propensity, what part sexual selection may have played in shaping risk-seeking behavior, and how risk-taking can be operationalized and measured when researchers are interested in studying risky behavior from a functional perspective.

Exploring Risky Behavior in a Life-History Framework

Life-history theory, a theory subset of evolutionary biology and behavioral ecology, argues that biological aspects of the life course result from trade-offs when allocating finite effort among survival, current reproduction, and future reproduction (Chisholm 1993). The underlying logic is that patterns of birth, growth, and death (i.e., life-histories) result from competing costs and benefits of different allocations at different times in the life cycle. At any given point, organisms can decide

whether to spend energy on their own bodies (i.e., somatic effort) or to spend energy in reproduction, which can be through attracting a mate (i.e., mating effort) or in caring for offspring (i.e., parental effort). Which patterns of expenditure are most effective for survival and reproduction depends on the environment the organism is facing: In environments with longer life expectancy (often including high environmental stability and low mortality rates), it might pay to invest effort in growth and development, whereas in an environment with shorter life expectancy (often including high instability and high mortality rates), it might be advantageous to reproduce earlier. Thus, variables in decision-makers' personal and ecological environment can determine adaptive individual differences in risky behavior due to differences in how we discount the future and which reproductive strategies are selected. Including such concepts from life-history theory has been shown to improve existing models of risk-taking. In a classic paper, Hill et al. (1997), for instance, could show that people with higher future unpredictability beliefs and shorter lifespan assessments were found to be more risk prone in their behaviors, even after accounting for classic statistical predictors of risk-taking (e.g., sex, age). Similarly, Sherman et al. (2016) showed that humans can internalize environmental cues of mortality risk (e.g., prevalence of violent and property crimes, registered sex offenders) already at an early age during childhood and that those cues can have an effect on subsequent risk perceptions and behaviors later in life during adolescence and adulthood.

There is good evidence that patterns of risk-taking are also linked to variables which are important life-history variables in and of themselves, such as sex, age, marital status, and parenting. Wang et al. (2009), for example, examined the effect of life-history variables on risk-taking propensity, as measured by the likelihood of engaging in risky behaviors in multiple evolutionary domains of risk. The effects of life-history variables on risky behavior were domain-specific, and there was support for the common observed sex difference, in which men showed greater risk-seeking tendencies than women. Older age,

parenthood, and a higher reproductive goal setting all reduced risk propensity in some of the studied evolutionary domains, but not others. Shorter subjective life expectancy was associated with an increased willingness to take risks in the mating and reproductive domain.

Understanding the Role of Risky Behavior in Mate Attraction

Viewed in the framework of evolutionary theory, human risk-taking shows some remarkable sex differences. This raises the possibility that risky behavior is a sexually selected trait. Typically, males in their teens and twenties not only are more prone than females of the same age to take risks of many different kinds (e.g., unprotected sex, extreme sports, binge drinking) but also suffer from the higher mortality rates associated with this behavior (Kruger and Nesse 2004). From a decision point of view, many of these risks not only involve an increased variance in payoff but also typically lead to a lower mean payoff than not taking the risk at all.

Sexual selection provides two rationales for why males engage in these risky behaviors, especially at ages of high fertility and high intersexual competition. First, the variance and skew in male mating success may favor risk-taking when there are high potential gains that outweigh high risks (e.g., via an increased likelihood of partner acquisition). Second, males might take risks as a form of advertisement of their genetic quality to both females and rival males. Here, the argument for why risk-taking might be an honest indicator of quality follows the logic of the handicap principle: Risky behaviors are less of a danger to high-quality males than to low-quality males, high-quality males can afford to take such risks more often, and thus rivals and potential mates should use risk-taking as a cue to partner quality.

Wilke et al. (2006) tested some of these ideas by recruiting both singles and individuals in stable relationships. Young men and women rated how attractive they would find it if a potential partner engaged in various risky activities. Interestingly, not only men but also women reported that they found recreational and social risks as attractive

and other forms of risk-taking (e.g., gambling, health) as unattractive. This indicates that risk-taking is attractive to the opposite sex in some domains but unattractive in others. Both sexes were relatively accurate in predicting what kind of risky behavior would be attractive to a potential opposite sex partner if they themselves would engage in this activity, and individuals in stable long-term relationships showed positive assortment for risk-taking behaviors. This indicates that people with similar risk attitudes might have a greater likelihood of encountering each other or that there is generally higher mate compatibility between such mates.

Measuring Risky Behaviors Within Evolutionary Content Domains

Is someone who takes high financial risks (e.g., investing money in a speculative stock) also more likely to risk harm to his/her own health (e.g., smoking) or more prone to engage in dangerous sport activities? Not necessarily. The old conception that individuals differ in a situation-consistent and domain general level of risk propensity has been largely abandoned in the behavioral decision sciences (see, for instance, Hanoch et al. 2006). New methodologies have been developed that can not only distinguish the propensity to take risks in different domains but also construct integrated risk attitudes based on peoples' risk perceptions and levels of perceived benefit regarding a particular behavioral activity that involves risk.

From an evolutionary point of view, risk-taking behavior should be viewed as domain-specific due to the recurrent and enduring risks in the environment of evolutionary adaptedness that shaped human risk propensity, and risky behavior itself should be conceptualized as variations in payoff distributions within specific domains of adaptation. To test this, Wilke et al. (2014) created a large set of risky modern-day analogues of qualitatively similar actions in recurring problem domains of the ancestral environment that were potentially beneficial but also costly to survival and reproductive success. Multiple risk behavior questionnaire items were

pooled into individual risk domains that were generated from a textbook analysis of the fields of biological anthropology and evolutionary psychology. Each evolutionary risk domain was covered by various diverse activities and subdomains within this area. The psychometric analyses from Wilke et al. (2014) resulted in an evolutionary domain-specific risk scale that assesses risky behaviors in a total of ten content domains: between-group competition, within-group competition, status-power, environmental exploration, food selection, food acquisition, parent-offspring conflict, kinship, mate attraction, and mate retention. The authors found that respondents' degree of self-reported risk-taking was indeed not consistently risk-seeking or risk-averse across evolutionary content domains and additionally surveyed life-history variables had domain-specific effects too. Overall, men were more risk-seeking than women, but interestingly not in all domains. Women were more risk prone in the domains of food selection and kinship. Study participants that reported not being in stable long-term relationships had higher risk propensity in the domains of mate attraction and mate retention. As supported by other studies, age, reproductive goal setting, parental status, number of siblings, and birth order all affected reported risk propensity.

In subsequent research, Jarecki and Wilke (in press) investigated the cognitive processes with which such different risk-taking tendencies across content domains can be reliably produced. Such work is necessary to close the existing gap between proximate (mechanistic) and ultimate (functional) considerations of decision-making under risk and uncertainty. Specifically, Jarecki and Wilke (in press) compared three cognitive process models with regard to how attributes retrieved from memory could account for the found domain differences and how specific types of informational risk cues and their respective frequencies are associated with peoples' domain-specific risk behaviors. Results suggested that specific types of situational attributes are most relevant for the found domain differences in risk-taking propensity.

Conclusion

The evolutionary psychological sciences provide a rich framework for studying risky behavior as they highlight what risk domains should be studied, what influence life-history variables have on risk propensity, and why young men, typically, are more risk-seeking than women.

Rite of Passage

Definition

A ceremony known as the rite of passage denotes a person's leap in life. It marks all important or milestone events, or it is used to pronounce the tumultuous transition from adolescence to adulthood and includes essential transitions in one's life such as births and beginnings, initiations, partnering, and endings or death.

Theoretical Framework

A number of models have been devised to define the process of shift in boundaries while maintaining various aspects of organizational regulation and social strength (Lewin 1951). Considered together, these models tend to provide an explanation to the shift of individuals or groups, at important stages of life and assuming new roles and responsibilities. Therefore, crossing social boundaries is a considered unavoidable outcome of social change, and such boundary transitions, if unfettered and unconfined, tend to challenge a person's social status.

It has been asserted by Van Gennep (1960) at the start of the twentieth century that even

though every society had distinct content of social transformations, an attribute of social transformation is that their form or pattern remained universal. Those societies that were entirely distinct from each other had almost the same formal rites of passage that allowed individuals or groups of individuals to adjust their personal status. A rite of passage refers to an event in which an individual moves from a certain condition of life experience to another, from a certain phase in life or a state of social status, to a more sophisticated one (Van Gennep 1960). A rite of passage essentially signifies significant personal life experiences or life crises. These include, for instance, life-changing events like marriage, parenthood, or demise of a closed one. In addition, a rite of passage may also be present in other critical life experiences, like academic accomplishment or becoming an official member of an occupational group or profession.

A three-staged model of social transition was put forward by Van Gennep (1960). The model was formulated using a separation stage (when the person or group is eliminated from an earlier state), a transition stage (the liminal stage, a social limbo in which the person may establish a close relationship with other group members), and an incorporation stage (which involves integrating back into the society in a novel state). Henceforth, a rite of passage signified variations in social status, which involved intricate symbolic ceremonies and/or simple practical occurrences, determined by the nature and situation of the transition (Draper 2003). For example, it was observed by Froggatt (1997) that certain stages of a rite of passage may be more noticeable depending on the kind of life event being experienced. The separation stage would be more obvious while mourning, the transition stage would be more obvious while experiencing parenthood, and the incorporation stage would be obvious in the early period of marriage. The purpose of rite of passage related to these life events was to decrease their possible adverse effects on the individual and on social order and solidity.

Conclusion

The ceremonies, rules of society, and culture enable transitions in one’s life. These transitions also authenticate the stability and direction of social groups by allowing the acceptance of social and cultural transition and by evading interpersonal or group conflicts. It is established that both groups and individuals change with the passing time, the level of their status and wisdom changes and they also acquire new skills and abilities. The formation of new social groups means new transitions. Therefore, negotiation has emerged as a necessary element of an effective transitional procedure.

Definition

Thesis originally developed by anthropologist Chris Knight on the important consideration of novel forms of group cooperation, and corresponding conflict, in the emergence of human language, analogous to signaling in other species.

Introduction

In this entry, I discuss the ritual/speech coevolution hypothesis for the evolutionary emergence of spoken language. This brings the main theory on the evolution of animal signals to bear on the question of language origins. Our closest primate relatives are fundamentally constrained in their ability to mimic or produce novel vocalizations, under pressure to maintain reliability in their signals. The ritual/speech coevolution theory explains how those selection pressures were relaxed in the case of human evolution through the generation of novel levels of in-group trust.

The Problem of Cooperation in Communication

Ritual/speech coevolution is a hypothesis explaining the evolutionary emergence of spoken language. It rests on the assumption that language can only evolve given novel conditions of social

cooperation widespread across human communities – effectively cooperation between strangers. In the contexts of human evolution, the only medium for securing such cooperation within and between groups was costly ritual (cf Durkheim 1912; Knight et al. 1995; Maynard Smith and Szathmari 1995; Deacon 1997; Rappaport 1999; Irons 2001; Alcorta and Sosis 2005; Knight and Lewis 2017).

Ritual/speech coevolution brings to the problem of language origins the main body of theory applied to the evolution of animal signals. Signal evolution theory deals with the emergence, function, and design of animal signals (Maynard Smith and Harper 2003). Focused on social interaction and behavior in the world, signal evolution is necessarily political in its approach. Central debates concern the honesty and reliability of signals (Zahavi and Zahavi 1997), manipulation and mindreading (Krebs and Dawkins 1984), and the effects of shared versus conflicting interests in outcomes (Maynard Smith and Harper 2003).

Among primates generally, tactical use of deception is predicted by neocortex volume (Byrne and Corp 2004), a finding consistent with the Machiavellian intelligence hypothesis – the idea that intelligence evolves under pressure to deal with social challenges. Humans are clearly Machiavellian in terms of political alliance formation and capacities for deception. Issues of trust and reliability are critical to any understanding of language origins.

While apes and monkeys have rich repertoires of calls, they seem to be severely restricted in their ability to mimick or to produce novel vocalizations (Fitch and Zuberbühler 2013). In particular, when phonating, they lack neural control over articulators such as the lips, tongue, soft palate, etc. This means that our closest relatives are unable to manipulate vocalizations at will. No monkey or ape has an inflexible tongue, but when communicating it leaves the tongue out. Knight and Lewis (2017) draw on signal evolution theory to explain why. While sound – unlike visible gesture – carries over distances, goes around corners, and works in the dark, in these contexts listeners lack corroborating evidence of reliability. It makes sense then that vocalizations

tied to bodily and emotional states will be perceived as more reliable than those which can be altered at will. Mistrusting one another's scheming, Machiavellian minds, primates ignore the all too-flexible tongue, preferring to rely on the evidence of their own eyes and ears. In this view, apes are “too clever for words” (Knight 1998: 72).

So the conundrum of speech and language evolution is to explain how and why natural selection, in the human case, switched from quarantining the primate tongue – excluding it from all but a marginal communicative role – to developing and fine-tuning that same tongue's role as the most important speech articulator of all.

Signal evolution theory contrasts two divergent trajectories depending on the degree to which signaler and receiver share interest in the same outcomes. Where we find high-cost, repetitive, multimedia displays, we may infer a function in terms of social manipulation, conflict, and exploitation. Resistance by receivers sets up selection pressures acting on signal design. Signalers who encounter “sales resistance” are driven to respond by prolonging and repeating signals, increasing amplitude, and resorting to costly multimedia displays. Such extravagant advertisers include peacocks displaying to would-be mates or caribou bulls bellowing in the rut. Zahavi (1987) shows how the discernible costs of such displays enhance their credibility by tapping and hence testing the very reservoirs of quality that signalers are attempting to advertise. The evolution of high-cost signaling is driven by skeptical receivers pushing signalers to ever greater competitive effort to prove their quality.

By contrast, where we find low-cost, quiet, and efficient signals, a cooperative audience can be inferred. If signalers can afford to cut their emission costs, it is only because listeners are investing corresponding effort in receiving, decoding, and acting on signals. This implies that signalers and receivers significantly share interests. For such “conspiratorial whispering” (Krebs and Dawkins 1984) to evolve, signalers must be imparting useful information to receivers and those receivers are not expecting to be deceived.

The ultimate cost-cutting strategy would be to resort to purely tokenistic, wholly conventional

signals that can be processed categorically at speed – relieving listeners of the need to evaluate gradations in physical performance and signalers of such costly performance. According to Zahavi (1993), however, animal “conspiracies” are never sufficiently cooperative. Internal conflict and skepticism precludes selection for reliance on tokenistic “paper money.” Nowhere in the living world do we find purely conventional signaling – with the puzzling exception of human speech.

Turning to human symbolic communication, Knight (1998, 1999) argued that our ancestors developed divergent, formally contrastive types of communication along these two “high-cost” and “low-cost” trajectories: ritual and speech. Table 1 shows the diametric opposition of characteristics of each. On the basis of signal evolution theory, we can infer that speech emerged in a cooperative context while ritual did not. For speech to have evolved, “conspiratorial whispering” in the human case must have been anomalously trusting. By contrast, ritual – with its costly, inefficient features of redundancy and display – can only have emerged from a dynamic of conflict, manipulation, and exploitation.

The paradox here, in the light of nonhuman primate vocalization, is that the extremely low-cost, conventional codes of speech can easily leave listeners vulnerable to deception. With no

intrinsic link between sounds and their purely arbitrary meanings, words are routinely decoupled from emotional veracity or real-world stimuli. Despite speech having no intrinsic reliability, human conversation works on Grice’s “cooperative principle” (Grice 1969), with participants, even where they may be in some degree of social conflict, cooperating at the level of mutual conversational ends. If humans are on “speaking terms,” they expect intentional honesty. Somehow this new default of honesty – honesty in the deployment of volitional, conventional signals – became established. In the course of human evolution what were once frequency-dependent tactical deceptions became increasingly harnessed to a reversed social function: group-wide sharing of socially useful information.

This paradox can be unraveled if we consider that whereas speech is fundamentally interpersonal, ritual operates group-on-group and may function to demarcate boundaries of those groups (Cohen 1985; Harrison 1993). Experience of the high-cost, multimedia signals involved in ritual will differ according to whether the receiver is outside or inside the performing group. For outsiders, the costly signals are manipulative and exploitative, needing to overcome “sales-resistance” by impressing observers with the quality of performance. Among insiders, the “collective effervescence” (Durkheim 1912), aroused by singing, dancing, and musicking together, will intensify in-group trust and generate a sense of group identity as “We” (Rappaport 1999). Focusing on the emotional responses of individuals to ritual experience, Alcorta and Sosis (2005) show that the very costliness of undergoing ritual enables those individuals to demonstrate in hard-to-fake terms their commitment to the group.

There are two major emergent effects from such proto-ritual experience. First, the novel levels of in-group trust can now permit conventionalization and shorthand reference – volitional, conventional signals – in communicating among group members, now on the way to becoming a speech community. Secondly, in representing their coherent and enduring solidarity, ritual performers generate sacred, supernatural, and counter-intuitive concepts – the first gods

(Durkheim 1912; Knight et al. 1995; Rappaport 1999; Alcorta and Sosis 2005).

Roy Rappaport analyzes the form and features of ritual that make it “the social act basic to humanity” (Rappaport 1999: 31). Ritual overcomes the divisiveness of individually held beliefs. Defining ritual as “the performance of more or less invariant sequences of formal acts and utterances not entirely encoded by the performers” (Rappaport 1999: 24), Rappaport focuses on the unique conjunction of features in ritual. Ritual form permits the intersection of the symbolic with what is not purely symbolic. Ritual combines formal canonical messages – encoded by other than the performers – with the indexical signals, the current state, mood, and emotions of the flesh and blood performers. This “substantiation of form and ...informing of substance” mean that the establishment of convention is intrinsic to ritual. Without this, no social contract, moral order, or language could exist.

The function of ritual is not to differentiate between lexical meanings but to establish, for everyone, an overarching meaning – a meta-performative or Word – from whose subsequent fragmentation a limitless multiplicity of subsidiary meanings can be derived. Rappaport explains how apparently irrational nonsense – perhaps the endless repetition of just a few meaningless sounds – may “provide the ground, deeper than logic and beyond logic’s reach” upon which to establish sufficient collective authority and mutual trust to build up “the usages and rules of social life,” in turn enabling words to make sense.

While Rappaport did not have any very satisfactory model for the evolution of ritual (hence speech), Knight and Lewis (2017), within the ritual/speech coevolution paradigm, provide a specific evolutionary account. Words and grammar, they claim (Knight and Lewis 2017: 435), are “means of navigating within a shared virtual world. Singing, dancing, and other forms of communal ritual are necessary to join people together in such ideal or imagined worlds.” Language then will not even begin to evolve unless ritual action has already begun to establish intensified levels of community-wide trust in association with a shared virtual domain. This explains why nonhuman

primates, confined as they are to the brute world of physical facts, have no need of it.

Knight and Lewis explain how the generative principle for both words and grammar is the ostensive-inferential process underlying metaphor. In this view, symbolic communication “rests on the ability of listeners to infer relevant communicative intentions from expressions that, interpreted literally, are inadequate or untrue” (Knight and Lewis 2017: 436). Not only does language comprise zero or very low-cost volitional vocal signals, but at the level of both words and rules, lexicon and grammar, these amount to conventionally agreed “lies” or deceptions. Whereas nonhuman primates would simply reject these sound sequences, we humans instead search out the hidden implications and communicative intentions.

Knight and Lewis draw on hunter-gatherer ethnography to work out a model for the emergence of such socially agreed “deceptions.” Human abilities to manipulate pitch were first exercised in fooling outsiders: animals, whether these were prey being hunted (by men) or predators being evaded (by women and children). Song first – a communal polyphony of meaningless sounds – used to confuse and deter predators regarding numbers of hominins in groups, would have developed capacities for intentionally varying pitch. In such a context, the emotional solidarity among chorusing groups would override any dangers of deceptive use. Shorthand snatches of song, animal-sound mimicry, or pantomime dance steps could now begin to take on specific shared meaning. From there, a fully grammaticalized language could emerge with extraordinary speed, as long as the freedom to innovate – freedom to “say” one thing while “meaning” another – was maintained. What had blocked earlier hominins and hominids from any such grammaticalization process was “the burden imposed on all signals to incorporate some costly component to demonstrate reliability” (Knight and Lewis 2017: 445). Grammaticalization is based on a tendency to efficiency, but requirement of reliability in signals demands the opposite, increased cost. The release from this constraint frees the tongue and other articulators so they can be recruited to

increasingly efficient, conventionalized communication: speech.

Knight and Lewis (2017) aim to make their model testable by specifying, in detail, the “world’s first metaphor,” identifying it as a gendered ritual performance in which the core principles of primate politics are overturned. They argue that as female hominin ancestors faced increasing reproductive costs with very large-brained offspring, critical points of conflict occurred whenever an alpha male attempted to monopolize an imminently fertile (menstruating) female. This would have conflicted sharply with reproductive interests of both other females and other males. Ritual display developed as female coalitions mounted resistance to any would-be alpha, with the whole female group signaling their nonavailability to males through song and pantomime dance: we are the wrong species (animals); we are the wrong sex (males); and this is the wrong time (blood). By identifying their own “menstrual” blood as the blood of the game animals they wanted the men to hunt, women’s first morally authoritative ritual construct established categorical rules encompassing sex, kinship, and economics.

The specific model proposed here has the merit of testability. But the general ritual/speech coevolution paradigm has advantages (Power 2014). Firstly it offers a coherent basis for continuity with animal communication systems through theory of ritualized behavior. Secondly, regarding the archaeological record, it makes the clear prediction that the origins of language will be marked by evidence for ritual behavior (Watts 2014).

debate as to the evolutionary origins of religion is mostly divided between whether religions emerged over time as an adaptation selected through natural selection or that they are by-products of other psychological mechanisms, this section will specifically address some of those religious rituals considered by both theories to have plausible universal salience in the general development and maintenance of religious cultures worldwide.

Established rites, ceremonies, and customs performed publically and/or privately by individuals or groups as prescribed by religions.

Introduction

Religious and cultural rituals represent those observable activities and series of actions or behaviors requiring recitations, gestures, and the manipulation of objects as expressed by groups or individuals to demonstrate commitment to and in compliance with the accepted religious traditions and customs of specific communities. Religious scholars and social scientists agree that religious rituals are significant features of most world religions, influencing the cohesion of the cultural groups that practice them, providing practical benefits for individuals, and informing the practitioners' beliefs about life after death (Durkheim 1912, 2008; Wilson 2003). Although the ongoing

In-Group Functionality of Religious and Cultural Rituals

Religions, whether monotheistic or polytheistic, animistic or naturalistic, have throughout human history been expressed in remarkable varieties (Schmitt and Fuller 2015; Wilson 2003). Despite their tremendous diversity, religions share many common ritualistic activities. Religious rituals are seen as providing opportunities for community members to cooperatively and publically manifest shared beliefs, thus strengthening individual personal commitments to the group as well as substantiating and maintaining in-group bonds. Among the vast array of rituals practiced from the earliest religions through to the present day, certain key evolutionary benefits of ritualism emerge as essential such as the promotion of social cohesion and cooperation, unified beliefs in life after death via ancestor veneration, and the subordination of individuals' self-interest for the benefit of the group (altruism), among others. These represent common characteristics of religions and are all seen in various individual and group rituals to varying degrees of import (Kirkpatrick 1999).

Commonly practiced religious rituals are shown to increase the ability to bind groups together, engender trust and cooperation among practitioners, and allow for public demonstrations of allegiance and commitment to the group (Whitehouse 2012). According to Whitehouse, during human prehistory, group identity was based primarily on shared experiences and rituals,

which had the effect of producing greater levels of intragroup member confidence and trust. Ritualized eating or avoiding of certain foods or wearing of specific items of clothing or hairstyles allowed for inferences of common beliefs and trustworthiness even in strangers, which had the effect of spreading group cohesion and therefore religious cultures, more widely. Victor Turner theorized that traditional and modern religious rituals could be understood in terms of the two separate concepts of structure and *communitas* with the latter referring to an egalitarian community of individuals sharing moral claims and the former referring to a systematized set of roles community members occupied, differentiated by age, sex, and status (Wilson 2003). In this light, religious rituals provide communal, visceral, and emotional experiences that help communities and social structures to remain united, especially during those times when adherents transition between social status roles such as from adolescent to adult (coming of age), unmarried to married, married to widowed, and elder community member to deceased ancestor. In these universal life experiences, rituals enable religious community members to cooperatively and publically express mutual beliefs, share grief and joy, commiserate about the rigors and goals of the rituals, and create cherished group memories, in addition to strengthening in-group bonds. Historically, religions successfully unify communities under common sets of customs, institutions, and organizations when the majority of the people in the population are members of the predominant religious community (Richerson and Newson 1987).

Coming-Of-Age Rituals

Coming-of-age religious rituals vary considerably from religion to religion, from era to era, and geographically but all are meant to signify to the adolescents, their families, and the religious community at large that they are willing participants in the physical, emotional, and spiritual

journey from being a child of the group to an adult within the group and, when successful, assume their newly acquired and specific rights and responsibilities. These coming-of-age or initiation rituals often include extended periods of fasting, going without sleep, venturing into the wilderness alone, sequestration, memorizing and performing elaborate chants and dances, as well as physical alteration of the body such as scarification of the skin, shaving of the head, and piercing of body parts, among many others (Gennup 1960, 2004). For girls, religious rituals for coming of age often pertain to the onset of menses, with the community acknowledgment of their fertility and an increased set of expectations and responsibilities to keep sacred the sexual and reproductive customs of the group (Gennup 1960, 2004). For boys, acts of bravery and courage are required such as the hunting of predator animals, exposure to stinging insects or plants, and feats of strength and endurance including long runs or carrying heavy objects over great distances. There is the universal expectation that the successful adolescent initiate not only pleases their parents and religious community by completing the initiation rites but also pleases the god or transcendent power honored at the center of the religion's belief system.

Religious Burial Rituals

From the perspective of most of the world's religions, ritual disposal of the human dead brings closure for the surviving family and friends of the deceased, confers respect on the departed, and is believed to assist in their transition to the next life. The earliest evidence of human religious sentiments is the treatment of the dead. Early human behavior as demonstrated in ritual burial is thought to represent cognition of the states of life and death. Ritual burials of modern humans at the site of Qafzeh, Israel, contained 100,000-year-old skeletons that were stained with red ocher and whose graves included the mandible of a wild boar. The

placement of corpses in shallow graves along with common stone tools and animal bones indicates an emotional connection to the deceased and reveals a belief in an afterlife. These types of ritual burials are believed to have served a number of different goals, including honoring the dead and communing with gods and spirits (Whitehouse 2012). Human remains found in Turkey revealed evidence of funerary practices 8000 years ago in that the bodies were elaborately manipulated before burial (Whitehouse 2012). With respect to the further development of religious sentiments in mortuary practices, it is likely that funereal rituals developed over time, becoming clearer and more complex as the various religious beliefs in a hereafter expanded.

Gennep developed the theory that funereal rites accompanying life transitions consist of three structural elements: rites of separation, preparing the dying person and giving the last rite; rites of transition, such as the final burial of the corpse in the cemetery or the group; and the rites of incorporation, a prayer service offered with the intention of praying for the salvation of the deceased person's soul. As in the performance of other religious rituals, there seems to be an attenuated tendency during burial rites wherein the community members conducting the rituals summon or invite the god(s) and spirits to assist. It is as if the mystery of physical death and the yearning for the assurance of afterlife are issues the living cannot understand or attend to without supernatural assistance and only when the living adherents offer obeisance to their god figures can there be an expectation of the burial rituals succeeding.

Rituals and Health

Among the potential evolutionary benefits of religious rituals is increased physical health. There have been numerous studies showing that religious beliefs and practices increase individual health and other aspects of well-being. According to the researchers at Duke University,

religious rituals can function as anti-stress mechanisms (Paul-Labrador et al. 2006). They were able to demonstrate that individual prayer and meditation, as well as attending church services, reduces blood pressure, high blood pressure being a reliable index of psychological stress. As elevated blood pressure causes heart disease and heart disease is the number 1 killer in many developed countries, the scientists determined that prayers and rituals have the capacity to enhance health and lengthen life. If the individual benefits of ritual prayers and meditation are enhanced by the ritual activities of communal religious practices and by the culture as a whole, then the rituals can be seen as positive manifestations of group-level adaptations. However, some religious behaviors such as dangerous initiation and coming-of-age rituals involve potentially significant costs to individual members' health as well as to their religious communities writ large, suggesting that unless potentially dangerous and risky rituals provided significant advantages, natural selection should act against them.

Conclusion

Throughout human history, religious and cultural rituals have been used to promote in-group functionality, to challenge adolescents in coming-of-age rituals, and to provide solace and closure for loved ones with burial rituals and have been shown to positively promote physical and emotional health. While there may yet be no definitive answer to the question as to whether religion evolved as adaption through natural selection or emerged as psychological by-products, it is clear that the multiplicity of religious rituals throughout the world's religions attempts to address universal human concerns of life, death, and beyond.

Definition

Rivka Weinberg is a Professor of Philosophy at Scripps College in Claremont, California.

Weinberg received her Bachelor of Arts degree from Brooklyn College, City University of New York, and her Philosophical Doctorate degree from the University of Michigan, Ann Arbor.

Introduction

Rivka Weinberg's main areas of interest are ethics and metaphysics. Her areas of expertise include reproductive ethics, bioethics, theories of moral obligation, and the metaphysics of life and death. In December 2015, Weinberg published a book, entitled *The Risk of a Lifetime*, which incorporates much of her previous work in these areas and presents a cohesive argument for a new way of thinking about the permissibility of procreation. In this entry, Weinberg's early work that led to the development of her arguments in *The Risk of a Lifetime* will be highlighted, beginning with Weinberg's contributions to metaphysics. Her metaphysical views lay the foundation for her work in reproductive ethics, which will be reviewed in the second section, touching upon her theories of procreative justice and parental responsibility.

Part One: Metaphysics of Life and Death

The Nonidentity Problem

The nonidentity problem was posed by Derek Parfit (1984, Part 4) and picks up on three seemingly opposed intuitions about personal identity. The first intuition is that an act can be wrong only if it harms an existent or future person. The second intuition is that an act that confers a flawed existence upon someone, but existence that is still worth having, is not a wrong act (does not harm that person) compared to a world in which this person did not exist. That is to say that where a person's existence has some flawed qualities, if the person's life is preferable to the option of not existing, then they were not harmed by being brought into existence. The third intuition is that some acts that confer existence are wrong, even if they do not cause harm to the person they cause to exist or any other future person (for a full

explanation of the nonidentity problem, see Roberts 2015).

Weinberg is interested in this question because the nonidentity problem makes it difficult to discover who might be harmed by a reproductive act. In this case, philosophers have theorized that it might always be permissible to procreate as long as a person's life is likely to be worth living (Weinberg 2015). Weinberg thinks, however, that the nonidentity problem makes a mistake, which is the assumption that existence is "a good bequeathed by our ancestors" (2015). Instead, she argues, existence is simply a state of affairs, something everyone has and nobody needs, as she puts it (Weinberg 2013, 2015).

Existence as a Precondition for Interests

Thus, contrary to a common intuition and line of argumentation, Weinberg sees existence as neither a gift nor a benefit. She aims to break away from the idea that existence is itself a good thing and to encourage others to stop thinking of it this way as well. Instead, existence is a precondition to having interests of any kind (Weinberg 2013, 2015). One cannot receive a benefit unless one exists. So, existence is just the state of affairs of being able to receive benefits (or harms). Existence is the state of having interests in doing well or not doing badly.

Common Moral Principle

The view that existence is a prerequisite for having interests is in line with what Weinberg considers to be a common principle of morality, which is that one may have obligations to those who do or will exist, but not to hypothetical entities. Weinberg thinks this moral principle fits with intuitions about whom we might have duties or responsibilities to. Existence, she says, is required for being a subject and having interests. If one does not exist, one is of no moral importance even to oneself (Weinberg 2015). So, one may have moral obligations to those persons who exist, and one may have obligations to those persons who will exist, but we do not have obligations to those who may exist, but may not.

Weinberg's metaphysical positions are important because they frame her views on questions

of reproductive ethics. That existence is not a benefit, that it is merely a condition in which one is subject to having interests, and that hypothetical persons have no interests are main premises upon which many of her arguments about procreation stand. For example, in arguing against David Benatar's (457, 462) anti-natalism (2912) position against procreation, Weinberg (2012) posits that since only existent persons have interests, a person must exist for them to be benefitted or harmed. Nonexistence cannot benefit anyone; there is no subject to receive the benefit. Without a subject to receive the benefit, Benatar's argument that nonexistence is better than existence because it is a state of no harm should not be granted and the anti-natalist position rejected (Weinberg 2012).

Part Two: Reproductive Ethics

Procreative Justice

Weinberg is interested in questions about the morality of creating a child, rather than the morality of raising a child. In order to discover a principle of procreative justice, she attempts to redevelop John Rawls' original position (Rawls 2003; Weinberg 2002). This principle of procreative justice, she thinks, will shed light on which conditions may morally permit procreation. The reason that such a principle is needed, Weinberg argues, is that procreation actually involves a conflict of interests.

Procreative Conflict of Interest

Weinberg argues that procreative justice is primarily concerned with a distributive conflict of interests between parents and the children they will have (Weinberg 2002). Parents, she says, have an interest in procreating at the best time, from their perspective. This might mean being younger when procreating, for their personal health and lifestyle reasons. However, their child may have interests that conflict with these; a child may have an interest in being born later in their parents' lives, when they are more financially stable, for example. Weinberg thinks that this conflict of interest requires a principle by which the benefits

and burdens of procreation are justly distributed (Weinberg 2002).

Rawlsian Contractualism

John Rawls' contractualism is a theory formulated to address questions of distributive justice. Everyone that will be party to the result of a social contract enters into what Rawls (2003) called the original position, which is a position of undifferentiated vulnerability to social, economic, environmental, and other uncertainties. Rawls argued that in the original position, everyone would step behind a "veil of ignorance" about what their life conditions would be when the contract was created and the veil lifted. One would thus not know their race, religion, gender, sexual orientation, nationality, or any other differentiating quality that may lead to distributive injustices (and does in the real world). Therefore, everyone in the original position would need to assume that they might be the worst off in society and so have an interest in making sure that the worst off were still doing well enough to make such a position acceptable if one found oneself in it (this is known as the Maxi Min principle) (Rawls 2003).

Applying this method of arriving at distributive justice is challenging for questions of procreation. Parfit (1984), for one, does not think that Rawlsian contractualism can be applied to questions of procreation, because it is implausible for any of us to enter the original position and suppose that in the real history of the world we did not exist. He argues that questions of distributive justice in procreation will affect how many people exist, because some people who would have otherwise procreated may not be permitted to procreate under the resulting principle. If we assume that we will exist, this is like assuming that we will be the beneficiaries of a racist or sexist principle of distribution. Thus, the purpose of the original position would be thwarted, and the principle that resulted would be unjust.

Weinberg (2002) does not fully address these objections, but defends her use of Rawlsian contractualism by arguing that it does not require one to imagine one's own nonexistence, because issues of justice in procreation are restricted to

birth conditions and procreative liberty. Weinberg does not think that contractualism involves questions of justice in existence. She further argues that existence is not a distributable benefit. There can be no issues of justice between those who will exist and those who may exist, since those who may exist have no interests. There cannot be justice issues in not being created, because there is no subject of injustice.

A number of modifications to Rawls' contractualism are required to apply it to questions of procreation. Briefly, the nature of the parties to the contract will be "hypothetical future participants": those people who would exist and those who would be subject to the resulting procreative rules (Weinberg 2002). The veil of ignorance, for Weinberg, results in indeterminate identity, but not indeterminate existential status. Thus, Weinberg's original position includes only and all participants who will exist once the procreative rule is applied. In taking this approach, Weinberg attempts to sidestep Parfit's objection, but we can see how it poses a problem for her view. There are people who currently exist who may not exist if the procreative rule was applied prior to their birth, and there are people like them who may not exist in the future once the rule is in place. Each possible principle of procreative justice will include and exclude different groups of people who would exist under it. Weinberg does not address how these people would participate in the original position, but says it includes only the participants who will exist once the rule is in place and those who will be subject to procreating according to the rule. As Parfit pointed out, this may prioritize those who will exist in a similar fashion to prioritizing those who would benefit from being male in a sexist society and thus not reveal a just principle after all.

Setting this aside, however, when behind the veil of ignorance, participants will not know whether they are a prospective parent or a child (Weinberg 2002). Interestingly, because children are also future prospective parents, everyone behind the veil of ignorance will occupy both positions in the conflict of interests. While Rawls thought that information about probabilities should be veiled from the parties in the

original position, Weinberg (2002) thinks that probabilistic information is crucial to a procreative contract. She therefore argues that while individual information should be veiled, information about social and cultural norms, species information (i.e., “normal” human functioning), and other details must be known.

Finally, Weinberg (2002) thinks that for procreative justice, the concept of what is Good in life that participants in the original position should use needs to be specific and comprehensive, while also allowing a plurality of visions of a worthwhile life. The capability conception of the Good, under which certain conditions that permit the development and exercise of important human functionings are guaranteed or promoted, is the most appropriate choice, she thinks (Weinberg 2002; also see Nussbaum 1990). The capability conception of the Good, then, will inform a decision principle for the participants behind the veil of ignorance. This decision principle is a tool of self-interested and prudential reasoning, which directs participants in the original position to the principle of justice that will help to make their lives better, overall. Since participants will be using capability theory as their idea of a Good life, Weinberg (2002) reasons that the procreative decision principle they decide upon will be “maximizing capability” or “MaxC.”

In the procreative original position, children and prospective parents are represented and, Weinberg thinks, interchangeable in the sense that each participant will occupy both positions to her procreative conflict of interest. As such, MaxC is not just interested in the maximization of the child’s capabilities from birth; the parents must also enjoy a maximization of capabilities through procreation. Weinberg (2002) thinks that MaxC leads to interesting answers to important procreative questions. For example, she thinks that MaxC shows that the first-born child increases parental capability in a way that no subsequent child can (Weinberg 2002). With each additional child, parental procreative interest and the maximization of parental capabilities decrease. Thus, MaxC seems to encourage procreation, but perhaps places a limit on how many

children parents could have and still experience capability maximization.

However, taking this position indicates that Weinberg has placed special emphasis on parenting as a capability enhancer without providing an argument to support this value judgment. She states that not procreating inflicts “all kinds of losses” on a person, of a biological, emotional, and social nature (Weinberg 2002). Not procreating, she says, takes “a sharp, deep bite out of one’s capability to achieve a life of human flourishing” (Weinberg 2002). Weinberg presents this statement as factual, which indicates that she may not have considered that the participants in the procreative original position might severely restrict procreation (to only some individuals, say) or rule it out entirely. It also indicates that she may not have considered that parenting even one child may decrease capability, rather than maximize it. By assuming that parenting will be recognized as a significant contributor to human flourishing by participants in the original position, Weinberg begs the question of procreative permissibility.

Leaving this challenge for Weinberg’s account to the side, the principles of procreative justice that she thinks MaxC would yield from hypothetical future participants in the procreative original position are as follows:

i. *The obvious principle*

The obvious principle prohibits procreation that undermines everyone’s interests, such as teenage pregnancy (Weinberg 2002).

ii. *Procreative balance*

The balance principle permits procreation when it is not irrational for a parent to accept the risks their procreation imposes upon their prospective children in exchange for permission to procreate (Weinberg 2002).

iii. *Motivation restriction*

The motivation restriction requires that procreation be partially, yet prominently, motivated by a desire to raise, nurture, love, and care for the child once it is born (Weinberg 2002).

These three principles of procreative justice derived from MaxC are central to Weinberg’s

position on procreative permissibility and figure prominently in *The Risk of a Lifetime*.

Theories of Parental Responsibility

Another issue central to Weinberg's work is the source of parental responsibility. She considers many prominent theories of parental responsibility and rejects them, before presenting her own hazardous materials (HazMat) theory (Weinberg 2008). Briefly, these accounts are as follows:

Voluntary Commitments

The voluntary commitments theory states that parental responsibility is bestowed upon people who voluntarily decide to become parents. This would include people who become intentionally pregnant, people who adopt, and people who accidentally conceive but opt to continue the pregnancy and become the child's parent. However, because some conceptions are accidental and unwanted, it is possible for some children to be born without anyone being parentally responsible for them according to the voluntary theory. While some philosophers would accept this result as not particularly problematic (because, e.g., the State assumes responsibility until such a time as another voluntary [adoptive] parent comes forward), Weinberg (2008) thinks this result is unintuitive and an insurmountable problem with the voluntary commitments theory.

Intent to Raise

On this theory, parental responsibility is bestowed upon those people who intend, often before a child is conceived, to raise the child. This would include people who become intentionally pregnant, people who adopt, people who conceive accidentally but decide to keep the child, and people who conceive with the assistance of a gestational surrogate, for example. Weinberg thinks that, like the voluntary commitments theory, the intent to raise theory is problematic because it allows some children to be born without anyone being parentally responsible for them. Additionally, this theory is vulnerable to problems with knowing and discerning people's intentions (Weinberg 2008).

Genetics/Gestation

On the genetic and gestational theories, parental responsibility falls upon whoever's genetic material is used in the creation of the child or whoever gestates the fetus, respectively. The genetic theory of parental responsibility would include anyone genetically related to the child, which might be two parents involved in unassisted procreation, one parent plus an egg or sperm donor, or up to three people, in the case of one assisted reproductive technology in which an older woman's ovum is injected with cytoplasm from a younger woman's ovum; once inseminated, the resulting embryo contains three strains of DNA (see Connor 2014). Weinberg (2008) does not fully reject the genetic theory of parental responsibility, drawing on it heavily in her HazMat theory, though she finds it problematically simplistic.

The gestational theory bestows parental responsibility upon whoever has gestated the child. Though the gestational theory has been applied in some custody contests involving gestational surrogates, it does not capture the entirety of parental responsibility, even intuitively. Since only females can currently gestate a child, this theory would leave the male contributor to a child's existence without parental responsibility.

The HazMat Theory

Weinberg's (2008) hazardous materials (HazMat) theory bestows parental responsibility upon all people, by virtue of our possession and high degree of control over our own gametes. She considers gametes to be hazardous material because they can join with other gametes and grow into "extremely needy, innocent persons with full moral status" (Weinberg 2008). These dangerous possessions, she acknowledges, are not ours by choice; we have gametes as a biological function of our species. However, she argues that our risky actions involving our gametes, such as sexual intercourse, are under our control (most of the time), and therefore we are parentally responsible for the results of our gametes meeting with others. Weinberg (2008) thinks that the HazMat theory is in tune with many of our intuitions about parental responsibility, such as holding people

responsible for a pregnancy or child resulting from a failure of birth control.

The HazMat theory is similar to the genetic theory because it follows genetic relatedness to discover parental responsibility. Weinberg provides a different and more nuanced justification for her HazMat theory, by focusing on our risk behaviors, but the result is the same: whoever is genetically related to the child bears (non-transferable) responsibility for the child's existence.

Transfer of Parental Responsibility

Weinberg finds the transfer of parental responsibility to be particularly problematic and potentially impossible. Since the HazMat theory tracks genetic relatedness to discover parental responsibility, it seems that Weinberg would reject the notion of a transfer of responsibility because genetic relations cannot be altered. She does not acknowledge this similarity, however, and because her argument against the transfer of parental responsibility may betray a prior commitment to the importance of biological relatedness, her arguments may again be question begging.

Gamete Selling and Donation

In considering whether parental responsibility can be transferred, Weinberg (2008) presents two cases (Joe Blow and Joe Spermdonor) that she thinks are morally equivalent; if we find parental responsibility in one of these cases, then we must find it in the other. The case of Joe Blow involves accidental conception resulting from a broken condom. The case of Joe Spermdonor involves the donation or sale (though these may not be equivalent acts) of sperm. According to Weinberg's (2008) HazMat theory, both Joes are responsible because of the risky activities they engaged in. Since the HazMat theory states a child that results from our (voluntary) risky behavior involving our gametes, no further argument is required to establish Joe Blow's responsibility. If one disagrees that Joe Blow is parentally responsible, it must be that one does not accept the HazMat theory. Further argument is required, however, for the justification of Joe Spermdonor's

responsibility, because on some notions of risky behavior involving gametes, Joe Spermdonor would not qualify. This is because Joe S. gives his gametes to an agency that undertakes to secure and preserve them and make decisions about when they may be used.

Weinberg uses an argument from analogy to try to defend her view that Joe S. is responsible: if a company has enriched uranium to dispose of and gives this uranium to another company for safe-keeping and something goes wrong in that company causing a major explosion, we would not absolve the first company from their responsibility for the uranium. This, however, may be counterintuitive. When a company manufactures a gun, and a person purchases that gun and uses it to murder someone else, we do not hold the company that manufactured the gun responsible for the murder. There are many instances where we permit the transfer of responsibility for dangerous materials or weapons; our gametes may be no different.

However, if we accept Weinberg's argument that giving sperm to a donation facility does not absolve Joe S. of responsibility for his hazardous material, then we may also conclude that Joe S. has parental responsibility for a child that is produced using his sperm. Weinberg (2008) argues that Joe S. knew, or had good reason to think, that his sperm would be used to create a child, and so by giving his gametes away, he voluntarily permitted his gametes to potentially come into contact with others. This result, Weinberg allows, may be too counterintuitive to accept (or unwelcome, given that many people using assisted reproductive technologies like sperm or egg donation do not want the donor to have responsibility for the resulting child and vice versa). However, she challenges that if a sperm donor was the only match to a child needing a bone marrow transplant, we may not be willing to absolve the donor of responsibility toward the person created from their gametes (Weinberg 2008). In this case, we can see that Weinberg finds genetic relatedness, more than risk behavior, to be an important factor in determining responsibility.

The Love Obligation

In addition, Weinberg presents the argument that responsibility is non-transferrable partly because love is a parental obligation, and the people whose gametes were used to create the child can provide a special kind of love that others cannot provide. Weinberg (2008) thinks that we can assume that love is one of a child's basic needs and that this creates an obligation upon the parent to form a relational bond of loving and caring. It is unclear, she says, that the responsibility to relate with a particular feeling toward another person can be coherently transferred; the parental responsibility to love one's child, she argues, must involve *one's* love – not anybody's love (Weinberg 2008). Passing responsibility to stand in a particular emotional relation toward another person may be impossible.

However, Weinberg's argument that the love given to a child must be the love of the people whose hazardous materials were used in its creation seems to assume a special value in genetic relatedness. That there is something special about being someone's biological parent (or child) is a common bias. There are many reasons to be suspicious of the assumption that the love of a person who is genetically related is obviously or naturally superior to the love of a person who is not genetically related; cases of abuse, neglect, or abandonment make this clear. Thus, it seems that while children require love, this requirement may be satisfied by the love of people of various kinds, genetically related or not.

Weinberg (2008) is interested in arguing that Joe Spermdonor has an obligation to love the children who are created as a result of his sperm donation and that he cannot transfer this love obligation to others, such as the parents who request and utilize his sperm to create children. One may wonder whether, even if one agrees that Joe Spermdonor holds parental responsibility toward the children created from his gametes, love can be an obligation. As Weinberg (2008) describes it, the love obligation requires one to stand in a particular emotional relation to another. This may not be a coherent understanding of love, nor of obligation. Love seems to be something significantly different from the kind of action

that can be made obligatory, as it is an emotional state. One may be obliged to perform acts that look like love: taking care, providing for needs, giving support, etc. However, as Harry Frankfurt (1988, p. 85) says, "it certainly cannot be assumed that what a person cares about is generally under [their] immediate voluntary control." Thus, it is not clear that one could be obliged to give the feeling of love (or create the feeling in oneself).

Conclusion

Weinberg's work covers many important questions about reproduction and parenting, which have only been touched upon here. The ideas that have been covered form the basis of the arguments she presents in *The Risk of a Lifetime* and elsewhere. Weinberg's theories present new, though not uncontroversial, ways of thinking about and understanding the metaphysical nature of existence, procreative justice, and parental responsibility.

Definition

RNA is one of the two nucleic acids produced by cells.

Introduction

Friedrich Miescher first discovered nucleic acid in 1868. There are two types of nucleic acids. Deoxyribonucleic acid (DNA) has the blueprint to encode all the proteins in the biological world. DNA does this via another set of nucleic acid called RNA (Crick 1970). RNA plays essential roles in protein synthesis, gene regulation (by various noncoding

RNAs), rRNA processing (by snoRNA, i.e., small nucleolar RNA), and catalytic functions (by ribozymes).

RNA Structure

RNA is a single-stranded polymer of ribonucleotides. Ribonucleotides have three components: ribose sugar, one of the four nitrogenous bases (adenine, uracil, guanine, and cytosine), and a phosphate group (Fig. 1). The 1' carbon molecule of the ribose sugar (ring structure made of five carbons and one oxygen atom) attaches to the nitrogenous base and 5' carbon molecule to the phosphate group. The phosphate group forms a phosphodiester bond with the 3' hydroxyl group of the next nucleotide. Thus, backbone of the RNA molecule is formed by ribose sugar and phosphate in succession. Typically, RNA is single-stranded; however, there is extensive

RNA, Fig. 1 Structure of RNA (S-ribose sugar, P-phosphate group)

pairing between the complementary bases within a RNA strand. So, RNA has the ability to fold and form three-dimensional structure. This folding is essential for certain functional aspects. RNAs form highly organized complexes with various RNA-binding proteins to form ribonucleoproteins (RNPs) which are the functional forms of RNA.

Functions

Protein Synthesis

Protein synthesis requires two important steps, namely (Fig. 2):

- (a) Transcription involves transfer of information from DNA in the form of a genetic code into a new molecule of mRNA.
- (b) Translation where the nucleotide sequence on the mRNA is translated (language changed) to amino acid sequence of protein.

Three kinds of RNAs, namely, mRNA, rRNA, and tRNA, play important roles in protein synthesis. mRNA (messenger RNA) carries the message for protein synthesis in the form of series of “three base codes” (codon), from DNA to the cytoplasm. rRNAs (ribosomal RNAs) form the molecular machines called ribosomes, which, after attaching to mRNAs, start protein synthesis. tRNA (transfer RNA) recognizes the transcribed code and adds appropriate amino acid (building block of protein) according to the code (Chapeville et al. 1962).

During transcription, RNA polymerase II reads one particular gene of the DNA and complementary base addition generates pre-mRNA. Pre-mRNA is then edited by addition of methylguanosine in its 5' end and polyadenylates in its 3' end, called as capping and tailing, respectively. Capping protects the mRNA from attack by ribonucleases, and tailing is important for its transport from nucleus to cytoplasm for translation. The noncoding parts of pre-mRNA (known as introns) are removed by a process called splicing. This process is executed by a

RNA, Fig. 2 Overview of protein synthesis

large complex called spliceosome, which comprises of snRNAs, splicing factors, and numerous RNPs. A single gene can give rise to multiple protein types by the process of alternative splicing, where different set of introns are removed (Early 1980). After splicing, only the coding segments (exons) remain to form the mature mRNA. This mature mRNA is transported to the cytoplasm via their binding with cap-binding proteins (CBP) and transcription export complex (TREX), present in the nuclear pores.

Once the mRNA is in cytoplasm, ribosomes bind to it and translation begins. This process is divided into three broad phases: initiation, elongation, and termination (Crick 1958). In eukaryotes, first there is formation of an initiation complex comprising of the 40s subunit of ribosome, eukaryotic initiation factors (eIFs), and nucleoside triphosphates. This initiation complex recognizes the 7-methylguanosine cap at the 5'

end of mRNA. With the help of CBP and eIFs, the ribosome binds to the mRNA.

A charged initiator tRNA carrying the amino acid methionine (Met-tRNA_i) binds the IF. tRNA becomes charged by binding with the amino acids (methionine, etc.) by the help of enzymes aminoacyl tRNA synthetases. After binding of the Met-tRNA_i to the IF, the ribosome moves from 5' to 3' end of the mRNA in search of the start codon AUG. Once the AUG is identified, the accessory proteins (like CBP and IF) dissociate, and the 60s subunit of ribosome binds to the smaller subunit and Met-tRNA_i. This step is the beginning of the next step (elongation) of the translation process (Fig. 3).

The larger subunit of ribosome has three compartments, A site (aminoacyl site for binding of aminoacyl tRNA), P site (peptidyl site binds tRNA with amino acid that has formed peptide bond with growing chain however is

RNA, Fig. 3 Detail process of protein synthesis showing different types of RNA. mRNA transcribed from DNA undergoes posttranscriptional modification in nucleus and then is transported through the nuclear membrane to cytoplasm, where the translation process is carried out. tRNA binds with the amino acid by the help of enzymes aminoacyl tRNA synthetase. tRNA carrying the amino acid binds to mRNA (by codon-anticodon interaction) at the A site on the ribosome (except Met-tRNA_i which binds to P site directly) and then sequentially at P and E sites (see text), gradually increasing the length of the peptide chain. The dotted ribosome shows the future position of ribosome as the translation process proceeds

not dissociated from the tRNA), and E site (exit site releases the dissociated tRNA). These compartments also extend to the smaller subunit. The charged tRNAs bind sequentially to A, P, and E sites and in turn add amino acids to the growing polypeptide chain (Fig. 3). Exception to this is, first charged tRNA (Met-tRNA_i) that binds directly to the P site. As the ribosome moves on the mRNA, the three base codons are matched with the corresponding anticodons in the tRNAs. A peptide bond is formed between amino group of A site amino acid and carboxy group of P site amino acid by the enzyme peptidyl transferase (Fig. 3). When the ribosome encounters one of the three codons (UAA, UGA, and UAG), the synthesis of protein terminates as there are no corresponding tRNAs for these codons.

Gene Regulation

A diverse group of noncoding RNAs (ncRNAs) are involved in gene regulation at transcriptional and translational levels. These regulations may include heterochromatin formation, histone and DNA modification, and gene silencing. Important examples of ncRNAs are miRNA, siRNA, piRNA, and lncRNA.

miRNA (microRNA): These are of about 22 nucleotide long. They bind to specific complementary target sequence in the mRNAs and promote its degradation (in case of strong binding) or blocking of translation (in relatively weak binding). miRNA is formed as a primary transcript (pri-miRNA), which is broken down by ribonuclease called Drosha to form double-stranded pre-miRNA. RNA-induced silencing complex (RISC) is a multiprotein complex having a single-stranded miRNA guide, Dicer enzyme (endoribonuclease) and Argonaute proteins. Pre-miRNA is cleaved by the enzyme Dicer to form functional single-stranded miRNA which on binding to mRNA is cleaved by Argonaute (Bernstein et al. 2001). This process called RNA interference (RNAi) (Anandalakshmi et al. 1998) is one of the essential processes in gene silencing (Bass 2000).

siRNA (small interfering RNA): It is a double-stranded RNA and very similar to miRNA. It can

be introduced from outside of the cell. Function is through the RNAi pathway (Hamilton 1999).

piRNA (piwi-interacting RNA): They too are involved in gene silencing via RISC. piRNAs interact with piwi proteins of Argonaute protein family. piRNAs direct these proteins to the transposon targets and induce gene silencing (Klenov et al. 2011).

lncRNA (long noncoding RNA): These are more than 200 nucleotides long. They recruit chromatin remodeling complexes, thus actively involved in epigenetic modifications.

Evolutionary significance of RNA: Earlier RNA was considered as a poor cousin of DNA, but research in last 50 years show that life's origins on Earth started with RNA. The RNA Tie Club was formed by Francis Crick and some other scientists in 1955. This group seriously considered the important roles that played by RNA in evolution of life on the Earth.

According to the RNA World Hypothesis, RNA was the first self-replicating molecule during evolution (Scott et al. 2014). Thomas Cech and Sidney Altman independently discovered that RNA molecules could serve as enzymes by catalyzing chemical reactions in the cell. RNA adaptation (including RNPs, RNA editing, and RNAi) to a changing environment is thought to be responsible for subsequent diversification of life. Scott and his coworkers suggested 2',3'-cyclic phosphate version of nucleotides to be the prebiotic monomer to form polymer RNA abiotically (Lehman 2010).

Several attempts have been made for synthesis of RNA in abiotic environment. Experiment of Miller and Urey showed the synthesis of amino acids when mixture of gases was treated with electric current (Ferus et al. 2017). In 1960, Oró and his colleagues reported the abiotic synthesis of adenine (which is an important constituent of nucleic acids) from a hydrogen cyanide and ammonia (Roy et al. 2007).

In organisms, RNA evolves by undergoing certain processes (point mutation, insertions, deletions, recombination) that alter its sequence. Alterations in the RNA result in changes in the structural and functional dimensions of the organism (Lehman 2010).

Significance in Diseases

As RNAs have great impact over the function and regulation of cellular processes, their dysfunction give rise to many diseases including cancers.

Diseases Involving mRNA Metabolism

Mutation in splicing-associated proteins and regulatory RNAs causes numerous diseases, particularly neuromuscular and neurodegenerative diseases and cancers. Cis-acting mutations (involving the transcript from which protein is synthesized) at exon intron junction can disrupt normal splicing, because this region has the spliceosome binding site. Mutations in trans-acting (set of proteins having origin from different genetic loci) splicing components or the regulators can interfere with expression of several genes. Table 1 shows examples of diseases due to altered mRNA metabolism (Naryshkin et al. 2014; Sironi et al. 2002; Friedman et al. 1999; Růžicková and Staněk 2017).

Modification in alternative splicing events causes development of isoforms which promote tumorigenesis, including proliferation, invasion, and neovascularization. Mutations in core spliceosome components (SF3B1, U2AF1, SRSF2) have been studied extensively in hematological malignancies like myelodysplastic

syndrome, various myeloid neoplasms, and chronic lymphocytic leukemia (Malcovati et al. 2011).

Diseases Involving miRNA and siRNA

1. Neoplasms: miRNA is found to be associated with cancers like gastric carcinoma and pancreatic carcinoma (Sand et al. 2012). miRNA expression profiles are different in tumors from those in normal tissues. They differ among various tumor types. miRNAs can be oncogenic or tumor suppressors, depending upon their target mRNAs.
2. Neurological diseases: miRNA is mainly involved in neural developmental processes. Disruption of miRNA machinery in different neuronal and non-neuronal cells can cause neurological diseases. Examples include Purkinje cell in ataxia, oligodendrocyte in multiple sclerosis, and alpha calcium-dependent protein kinase type II expressing neurons in Alzheimer’s disease. Table 2 shows examples of mutation in central miRNA processing complexes causing neurological diseases in humans (Ling et al. 2010; Sunamura et al. 2018; Brás et al. 2017).

Particular miRNAs have also been linked to distinct disease processes like miR-206 in speeding development of ALS, miR-9 in spinal

Alzheimer’s disease in Down’s syndrome	miRNA dosage alteration (magnitude of expression)

motor neuron diseases, and miR-19 in pene-
trance of spinocerebellar ataxia type1.

3. Cardiovascular diseases: miR-1 is involved in the development of heart during embryonic life. It downregulates certain ion channels and has been linked to arrhythmias. Myocardial tissue in heart failure shows different miRNA expression profile from that of normal myocardium. Many of the vascular diseases are also caused by miRNA-related molecular changes.

Diseases Involving lncRNA

Correlation of lncRNA with various diseases has been observed, as suggested by its differential expression. It is particularly involved in patients of Alzheimer's disease, Huntington's disease, and Parkinson's disease. It is also seen to be associated with cardiovascular diseases.

Conclusion

RNA is vital for cell function and is dependent on countless mechanisms for its production, processing, and regulation. This involves plethora of sequence elements, RNA-binding proteins, and regulatory RNA species. All these complexities provide fertile ground for potential errors, which give rise to many disease processes; however, it also provides miscellaneous targets for possible therapeutic intervention.

Robert Axelrod is an American political scientist and professor of political science and public policy at the University of Michigan, USA. He is best known for his work on cooperation.

Education and Awards

Robert Axelrod received his bachelor of arts degree in mathematics in 1964 from the University of Chicago. He received his M.A. in political science in 1966 and his Ph.D. in political science in 1969, both from Yale University. He taught at the University of California, Berkeley, from 1968 to 1974, before joining the Department of Political Science and the Gerald R. Ford School of Public Policy at the University of Michigan (Axelrod 2018). For his academic contributions, he was awarded the 1980–1981 Newcomb Cleveland Prize of the American Association for the Advancement of Sciences for an outstanding contribution to science, the 1990 National Academy of Sciences Award for behavioral research relevant to the prevention of nuclear war, and the 2014 National Medal of Science (Axelrod 2018). He is also a member of the National Academy of Sciences, the recipient of a five-year MacArthur Prize fellowship (1987–1992), and the former president of the American Political Science Association (2006–2007). He was awarded an honorary Doctor of Laws degree by Harvard University, in 2015.

Research and Publications

Professor Axelrod's interdisciplinary research focuses on topics like international security and cyber-security (Axelrod 2018), with a particular interest in international peace and the threat of nuclear war, but he is best known for his work on the evolution of cooperation (Ostrom 2007). Axelrod has contributed to several areas of research, including public policy analysis (Axelrod and Cohen 2001), the sustainability of cooperation in various settings (e.g., Axelrod 1981, 1984),

international relations (e.g., Axelrod 1979; Axelrod and Keohane 1985), the use of simulation and agent-based modeling (e.g., Axelrod 1997a, 2006), and biological and sexual evolution (Axelrod et al. 2006; Axelrod and Hamilton 1981; Axelrod et al. 2004; Hamilton et al. 1990). In addition to numerous research articles, chapters, and commentaries, Professor Axelrod has published six books, including *Conflict of Interest: A Theory of Divergent Goals with Applications to Politics* (Axelrod 1970), *Framework for a General Theory of Cognition and Choice* (Axelrod 1972), *Structure of Decision: The Cognitive Map of Political Elites* (Axelrod 1976), *The Evolution of Cooperation* (Axelrod 1984, revised in 2006), *The Complexity of Cooperation: Agent-Based Models of Competition and Collaboration* (Axelrod 1997b), and *Harnessing Complexity: Organizational Implications of a Scientific Frontier* (Axelrod and Cohen 2001). Collectively, his work has been cited more than 98,000 times.

Axelrod's best known book is *The Evolution of Cooperation* (Axelrod 1984), which expands on an earlier paper by Axelrod and Hamilton (1981). This book drew on Game Theory, which refers to the investigation of strategy. Briefly, there are three broad categories of games within Game Theory: zero-sum games (i.e., where one player's gain always equals the other player's loss), positive-sum games (i.e., where there is the potential for mutual gain and conflict with respect to the division of gain), and negative-sum games (i.e., where there is the potential for mutual loss and conflict with respect to the degree of loss; see also the "Game Theory" entry in this volume). Axelrod (1984) used the game *The Prisoner's Dilemma* to investigate the conditions necessary for cooperation to occur. *The Prisoner's Dilemma* game involves a simultaneous choice where each player must decide to either cooperate or defect (i.e., betray) without knowing what the other player has decided. The basic premise is that both players are members of a criminal group who have been arrested and are being questioned separately by the police. Both players are offered a deal, whereby they can betray the other player (i.e., testify that the other committed the crime). If both players cooperate with each other (i.e.,

neither testifies), they will both serve a lesser sentence. If both betray the other (i.e., both defect), both players will serve the original sentence. However, if only one betrays the other, the betrayer will go free and the other player will serve a harsher sentence (see also "The Prisoner's Dilemma" entry in this volume). Axelrod (1984) found that the "tit-for-tat" strategy, where the player cooperates in the first round and then mimics the other player's first-round choice in all subsequent rounds, was the most successful strategy when playing a series of rounds against the same player, although defection was the most successful strategy in a single encounter. Axelrod (1984) makes inferences about how cooperation has evolved in complex social groups, noting that a cooperative disposition followed by reciprocation is adaptive when faced with repeat encounters with others.

In a later work, *Harnessing Complexity: Organizational Implications of a Scientific Frontier* (Axelrod and Cohen 2001), Axelrod and Cohen extend Axelrod's previous work on cooperation by examining cooperative processes in more complex settings, such as military personnel systems, contemporary information systems, and fighting the AIDS virus. The authors develop a framework that highlights the importance of comprehension with respect to system variations, interactions, and selection, and make eight specific recommendations to those looking to harness complex systems (see also Ostrom 2007): (1) Arrange organization routines to generate balance between exploitation and exploration, (2) build systems of reciprocal interaction that encourage trust and cooperation, (3) link processes that generate high variation to processes that select with few mistakes in ascribing credit, (4) assess strategies with respect to the spread of their consequences, (5) promote effective "neighborhoods" of systems, (6) do not propagate sizeable failures when only deriving small efficiencies, (7) proliferate valued criteria using social activity, and (8) look for shorter-term measures of success that can usefully stand in for broader long-term goals (Axelrod and Cohen 2001). Importantly, these recommendations differ markedly from more typical policy analysis that emphasizes "top-down control" by leaders who

then delegate to subordinates (Ostrom 2007). This and other work has provided a solid foundation that Axelrod and other researchers can build upon to investigate cooperation, complex intergroup relations, and various systems.

Conclusion

Robert Axelrod is an important figure in political science and public policy. His work is well cited and respected within the social sciences. He has had a tremendous, positive impact in advancing knowledge and theory in political, social, biological, psychological, and other fields, particularly with reference to public policy and the evolution of cooperation. His contributions will undoubtedly continue to prove invaluable as work in these areas advances.

Robert Axelrod's (1984) *The Evolution of Cooperation*

Definition

The Evolution of Cooperation (1984), by political scientist Robert Axelrod, is a book for a non-specialist audience based on four of the author's papers. The book's central question is: "Under what conditions will cooperation emerge in a world of egoists without central authority?" Axelrod answers this question using a computer tournament and simulations of the iterated prisoner's dilemma game, where a tit-for-tat strategy was successful. Based on these results, he

proposes general characteristics of strategies and interactions that promote long-term stable cooperation and discusses their societal and biological applicability.

Introduction

“When should a person cooperate, and when should a person be selfish, in an ongoing interaction with another person?” (p.vii), specifically “in a world of egoists without central authority” (p.3). This is the question that motivates *The Evolution of Cooperation* (Axelrod 1984). The book is based on a single, appealingly simple idea applied to different sociopolitical and biological contexts (Courtney 1985): many interactions take the form of a two-player iterated prisoner’s dilemma (IPD; Fig. 1) and the best strategy in such a game for both individual success and mutually beneficial long-term mutual cooperation is one of reciprocity, such as Tit-for-Tat (TFT). *The Evolution of Cooperation* summarizes and popularizes four of Axelrod’s papers that contain these findings: the results of computer tournaments (Axelrod 1980a, b), the supporting theory (Axelrod 1981), and the implications for evolutionary biology (Axelrod and Hamilton 1981). Axelrod uses these findings to assess what characteristics successful strategies share, describe how stable cooperation can

become established in an IPD, and suggest how to design interactions in the real world in order to promote cooperation.

Theoretical and Empirical Basis

The book’s argument is built around the two-player prisoner’s dilemma, a game whose key requirement is that payoffs follow the pattern $t > r > p > s$ (Fig. 1). That is, although the two players are better off collectively when both cooperate, the best strategy for any individual player in a single round is to defect. Axelrod’s insight is that the game can be continued over multiple rounds, i.e., an iterated prisoner’s dilemma (IPD), and that the probability w of playing another round with the same partner is key for the emergence of cooperation. In fact, when w is high, a player can do well by cooperating in the IPD.

Axelrod arrived at this result through two pioneering computer tournaments. Contestants submitted programs to play the IPD, accruing points each round according to the payoff matrix in Fig. 1. Each tournament consisted of five IPD games; each game lasted 200 rounds, and each strategy played each other strategy (including itself). To Axelrod’s surprise, the winner of the 14 programs in the first tournament was one of the simplest: Tit-for-Tat (TFT). A player using this strategy cooperates in the first round and thereafter copies its partner’s move from the previous round. In a second tournament with 62 programs,

Robert Axelrod's (1984) *The Evolution of Cooperation*, Fig. 1 A typical payoff matrix for a 2-player prisoner’s dilemma. The bottom triangle in each cell is the payoff to Player 1, the top to Player 2. The numerical payoff values are examples (those used in Axelrod’s

computer tournament), but the key criterion is that $t > r > p > s$. In the iterated prisoner’s dilemma (IPD), there is a probability w that the players interact in the next round, giving a probability $1/(1-w)$ of a sequence of interactions

where contestants knew the results of the first tournament, TFT also won.

But was TFT just successful in the particular “environment” of strategies in the two tournaments? That is, is it a *robust* strategy? To investigate a wider range of environments, Axelrod simulated the IPD over 1000 generations. Each generation represented one computer tournament, and the set of strategies was those that had competed in the tournament. A strategy's tournament score in generation i determined the number of copies of the strategy in generation $i + 1$, so strategies with proportionally higher scores gained proportionally more representation in the population. Once again, TFT was the winner. What features, then, facilitate TFT's robust success?

Characteristics of Robust Successful Strategies

Axelrod identifies four characteristics of TFT that allowed it to do well over a range of environments and that were shared by other successful strategies:

1. Niceness

Nice strategies are never the first to defect, i.e., they cooperate on the first move. Nice strategies are successful playing against each other, because they reap the gains from repeated mutual cooperation (but on the other hand, they suffer when playing against not-nice strategies).

2. Forgiveness

Forgiving strategies have a propensity to cooperate after being defected against. This allows them to avoid becoming locked into mutually destructive mutual defection.

3. Retaliation

Retaliatory strategies are provokable, i.e., they defect on their partner after their partner has defected on them. Retaliation has the potential to prevent further defection by the partner and thus to prevent exploitation of the retaliatory strategy.

4. Clarity

Clear strategies are easy for others to recognize. Other strategies do well by cooperating with

TFT and so benefit from recognizing it; this in turn helps TFT do well.

While successful strategies in Axelrod's tournaments and simulations undoubtedly had these characteristics, their universality has been shown to be sensitive to assumptions Axelrod made, such as the initial population composition in the simulation and the potential for strategies to make mistakes (Hoffmann 2000). These have been explored extensively in the subsequent literature, including by Axelrod himself (Axelrod and Dion 1988; Hoffmann 2000). In games with relaxed assumptions, TFT was no longer as dominant: for example, the potential for errors favored “Contrite TFT,” while a different starting population favored “Grim” (Binmore 1998).

Spatiotemporal Patterns of Cooperation

Axelrod recognizes that to understand when cooperation is a successful strategy, we need to examine its “chronology” by considering three separate questions about the sequence over which cooperation emerges. First, we can ask what makes strategies robust across environments, as I have discussed in the two sections above. Second, we examine initial viability: how can a strategy become established (i.e., invade a population) in the first place, particularly in a noncooperative environment? Third, we consider stability: how can an established strategy resist new strategies invading the population? I discuss the latter two points here.

Under what conditions can TFT invade a population (i.e., be initially viable)? Axelrod shows that the strategy always defect (All-D) cannot be invaded by TFT, so in a population of All-D, there must be some additional mechanism to allow TFT to become established. One mechanism familiar to evolutionary researchers is kinship (Hamilton 1964). In a population of related individuals, a cooperative strategy could do better than All-D and invade.

A second mechanism is spatial structure. One major inroad for TFT is that it does better playing against itself (due to mutual cooperation) than does All-D playing against itself (due to mutual defection). This means that if the probability that an invading TFT player interacted with another

invading TFT player were high, TFT could invade. This can occur if TFT players form clusters, making them more likely to interact with each other than with other strategies. Such spatial structure in a population may be physical or geographical (such that neighbors interact with each other more than do non-neighbors), or it can be more abstract, as in Axelrod's example of a cluster of companies producing the same products in a population where others' production is different.

Last in the chronology, under what conditions can a population of TFT be resistant to invasion by other strategies (i.e., be stable)? Axelrod demonstrates mathematically that neither a single player or nor a cluster of players using another strategy can invade TFT if w is sufficiently high, and that the threshold value of w depends on the IPD payoffs t , r , s , and p . That is, once cooperation is established, TFT can be stable even in a not completely cooperative environment.

Note that the conditions for "collective stability" that Axelrod uses are less restrictive than those for "evolutionary stability" (Maynard Smith 1982) and that if evolutionary stability is considered instead, then no pure strategy can be stable, and TFT can be invaded by "Suspicious TFT" (Boyd and Lorberbaum 1987). This underscores Axelrod's point that when w is high, there is no single best strategy in the IPD independent of the other player's strategy.

Implications for Promoting Cooperation

How can the principles from Axelrod's computer tournaments and simulations be applied, and in what situations are they relevant? Axelrod approaches this question from two angles.

First, given an IPD, what should a player do in order to be individually successful? Axelrod offers four suggestions:

1. Don't be envious

Many interactions are not zero-sum: instead of comparing yourself to the other player, compare yourself to how another strategy would be doing in your position. For example, a business buying from a supplier should not be envious of the supplier, since both parties can do well, and retaliation against each other would harm both.

2. Don't be the first to defect

The best predictor of success in Axelrod's tournaments was niceness.

3. Reciprocate both cooperation and defection

TFT and its variants are successful in a range of environments, because they elicit cooperation and are not readily exploited. To avoid retaliation leading to long-term feuding, "limited provokability" may be beneficial, i.e., a reciprocal defection of lesser magnitude than the first.

4. Don't be too clever

Does the other player know that you know that they know that you know what they will do? Chains of contingent behavior reduce a strategy's clarity, making suboptimal responses by the other player more likely. In an IPD, players do not benefit from hiding their intentions. For example, in the trenches of the First World War, truces emerged between British and German troops, but they nonetheless gave firing displays to indicate their willingness to retaliate if necessary.

Second, how can interactions be structured (the "strategic setting") in order to promote cooperation? Axelrod offers five suggestions:

1. Enlarge the "shadow of the future."

To increase w , interactions should be made more durable and more frequent. This could be achieved by spatiotemporal structure, e.g., clustering of small groups in space, having specialization on different roles, or decomposing larger interactions or goals (such as signing an arms control treaty) into smaller time steps. Conversely, reducing w can be destructive, exemplified by First World War troops being moved to different trenches, companies who are about to be bankrupted, employees about to be transferred, or politicians about to be defeated have little incentive to cooperate.

2. Change the payoffs.

The goal is to make long-term mutual cooperation more attractive than short-term defection. Restructuring the payoffs, for example, through creating institutions, can shift the interaction from

an IPD to a different game where cooperation is easier to achieve. The challenge is to determine effective payoffs: for example, if a government sets tough pollution limits, companies have an incentive to defect, but if the limits are not high enough, the payoff from companies' cooperation is low.

Axelrod summarizes the last three suggestions as "teaching values, facts and skills that will promote cooperation" (p.126):

3. Teach people to care about each other.
4. Teach reciprocity.
5. Improve recognition abilities.

These are all proximate mechanisms (Tinbergen 1963) that promote cooperation via TFT and that strengthen the four characteristics of successful strategies (niceness, forgiveness, retaliation, and clarity). As an example of teaching, Axelrod points out that in the First World War trenches, rotating troops passed on information to each other necessary to maintain cooperation. Feelings of caring can motivate nice and forgiving behavior, and better recognition abilities can facilitate both retaliation and clarity. Indeed, in the First World War, "the cooperative exchanges of mutual restraint actually changed the nature of the interaction. They tended to make the two sides care about each other's welfare" (p.85).

To what extent can these suggestions be applied to the real world (particularly politics, business, and international relations), as Axelrod proposes? One issue is that Axelrod's results are based on a simple IPD, and it is not always clear which real-world interactions do indeed take this form (Gowa 1986). For example, the First World War trench warfare may be a collaboration game instead of an IPD, and in many interactions there may not be a lack of central authority, as Axelrod supposes (Gowa 1986). A second issue is whether, for real-world interactions that are unambiguously IPDs, Axelrod's suggestions are actually feasible. For example, players must be able to demonstrate credible threats and respond flexibly, rapidly, and accurately to each other's behavior,

which may not be possible in international negotiations (Gowa 1986; Homans 1985).

Implications for Evolutionary Biology

Following a "strategic rather than genetic" (p.x) approach, Axelrod's concept of evolution is not restricted to true biological evolution (changes in gene frequency). His concept has two components: (1) "differential growth of the successful" and (2) "a source of variety" (p.170); the first of these suggests that he conflates evolution with natural selection. Regardless, Axelrod uses this "evolutionary" approach to investigate the invasion and stability of cooperation (discussed above), which were not taken into account in the original computer tournaments or simulations. In addition, despite the disclaimer avoiding genetics, Axelrod uses "evolution" as an opportunity to discuss cooperation in nonhuman organisms, in a book otherwise focused on human cooperation. The question, then, is how applicable to non-human organisms are (1) the IPD game and (2) the TFT strategy?

Axelrod argues that an IPD is possible whenever players can recognize and remember previous interactants, which is possible in many nonhuman organisms. However, this requirement can be bypassed if there are other mechanisms that facilitate repeated interactions, for example, if at least one of the players has a fixed location, as do many symbiotic mutualisms and territorial animals. Subsequent empirical work has shown that limiting spatial range as a way of increasing w may indeed promote cooperation in cleaner fish mutualisms (Oates et al. 2010). Future interactions are also more likely when an organism has a longer expected lifespan. Axelrod uses this principle to explain patterns of disease: for example, chronic infections become acute when hosts are likely to die, and genetic defects due to "cheating" chromosomes are more common when mothers are older.

However, others argue that there is limited empirical evidence for the IPD in nature, with many interactions not meeting the game's assumptions. For example, the IPD precludes

any sharing of information, but most interacting animals monitor each other's behavior (Dugatkin et al. 1992). In addition, the players' decisions may not simply be a binary choice to cooperate or defect: there may be a continuum, or there may be additional strategies such as choosing alternative partners (Raihani and Bshary 2011). Other interactions that appear IPD-like may not meet the payoff assumptions ($t > r > p > s$; Fig. 1): for example, in many cases there may in fact be no temptation to cheat (Riehl and Frederickson 2016). Measuring the values of the payoffs is a key challenge in assessing the validity of the IPD in nature (Raihani and Bshary 2011).

In cases where interactions do constitute an IPD, is there evidence that TFT has evolved and is successful? A handful of studies have demonstrated reciprocity in nonhuman animals, but are controversial because of the difficulty of measuring payoffs and demonstrating conditionality on others' behavior (Dugatkin et al. 1992; Raihani and Bshary 2011). Regardless, TFT appears to be uncommon in nature. Reasons for this include: (1) TFT requires a relatively high degree of cognitive complexity; (2) given such complexity, strict bookkeeping strategies like TFT may be less successful than other strategies for conditional cooperation, such as those based on emotional bookkeeping over a longer term; this may particularly be the case when payoffs are in different currencies for different players (Cheney 2011; Raihani and Bshary 2011).

Conclusion

Axelrod concludes that "the two key requisites for cooperation to thrive are that the cooperation be based on reciprocity, and that the shadow of the future is important enough to make this reciprocity stable" (p.173), and furthermore that "key to doing well lies not in overcoming others, but in eliciting their cooperation" (p.190). The concept of reciprocity has become so well incorporated into the literature on human behavior that can be difficult to appreciate its original impact.

Although Axelrod was not the first to put forward the concept of reciprocity in cooperative interactions (Trivers 1971), he made a major contribution by generalizing and popularizing it (Hoffmann 2000). *The Evolution of Cooperation* also made novel contributions in terms of considering the iterated game (Homans 1985), Axelrod's point that confrontation can be damaging (Courtney 1985), and his pioneering use of the computer simulation (Hoffmann 2000).

Much of the book's impact comes from its clear and straightforward message and simple game structure, helping make it a highly transmittable meme (Dawkins 1976). However, calling this message "Cooperation Theory," as Axelrod does, is somewhat misleading in its scope (Gowa 1986). The IPD models only one of many types of cooperative interactions (Dugatkin et al. 1992), and the extent to which the IPD accurately represents real interactions is under debate (Gowa 1986; Raihani and Bshary 2011). In other game structures, a diversity of mechanisms exist for maintaining cooperation among non-kin "in a world of egoists without central control" (p.69), such as indirect reciprocity and enforcement (West et al. 2007).

The book's reductionist approach also means that it has raised many issues for future research (Courtney 1985). One key assumption is that the IPD has two players, whereas an n -player game may better represent many real interactions; an implication is that the importance of direct retaliation is overstated (Binmore 1998). Another assumption is that the two players are equal, for example, in their perceptions of w as well as in the payoffs from a given action. Taking Axelrod's Cold War case study, the United States may be harmed less by its own spending on the military than would Russia (Courtney 1985) and may have different assumptions about how long the two countries will be opponents (Homans 1985). Unequal payoffs could lead to one player dominating the other, which could change the game such that that player acts as a central authority, which may be more common than Axelrod assumes (Gowa 1986).

The Evolution of Cooperation has an optimistic message: Axelrod claims that “the machinery for the evolution of cooperation contains a ratchet” (p.177), citing increasing norms of reciprocity in the US Senate as evidence. Judging this in January 2017, his conclusion seems naïve – but perhaps it is a question of choosing the appropriate timescale, and whether cooperation and conflict increase over time is an issue debated elsewhere (Pinker 2011). In addition, a major point the book makes is that many interactions or comparisons are not zero-sum, because both parties do well from cooperation (Courtney 1985; Gowa 1986). While this may be true in some scenarios, more recent research on the scale of competition shows that in many cases, individuals compete locally with potential cooperative partners and this hinders cooperation (Taylor 1992; West et al. 2006). Fitness is measured relative to others, and people have a tendency to compare their own payoffs to their neighbors’, which can lead to outcomes worse for all (Frank 2007).

Assuming, though, as Axelrod does, that players are in an IPD, to what extent should we follow his suggestions for promoting cooperation? A first concern is their effectiveness, which I have discussed above: relaxing Axelrod’s assumptions introduces complications, and in fact many other strategies in addition to TFT are successful (Raihani and Bshary 2011). A second concern is their morality, which, as Axelrod points out, may be in conflict with their effectiveness. For example, Axelrod shows how labels can be favorable for promoting cooperation, but can also lead to harmful stereotypes – and cooperation could also be promoted by forming a reputation as a bully. Importantly, Axelrod points out that many people may feel a strategy following the “Golden Rule” (“do unto others as you would have them do unto you”) is more moral than the “rough justice” (p.137) of TFT, but the former is less likely to promote mutually beneficial cooperation in the long run. This tension is intriguing and unresolved and would benefit from further attention.

In sum, despite these caveats, *The Evolution of Cooperation* offers suggestions for promoting cooperation that do apply to many scenarios. Axelrod’s interdisciplinary book is accessible and thought-provoking. Both its successes and limitations have stimulated continuing research on the evolution of cooperation.

Robert Hinde

Richard Wrangham

Department of Human Evolutionary Biology,
Harvard University, Cambridge, MA, USA

Robert Hinde (October 26, 1923–December 23, 2016) was a British behavioral biologist who studied the behavioral development and social relationships of birds, monkeys, and humans. He was the primary influence on a generation of behavioral biologists.

From 1940 to 1945, during World War II, Hinde was in the Royal Air Force, an experience that contributed to a lifelong disdain for war and concern to promote an ethos of peace. In 1948 he obtained a 1st class BA in Natural Sciences at the University of Cambridge, as well as a B.Sc. from the University of London. From 1948 to 1950, he conducted research for his D. Phil. in zoology at the University of Oxford, where he worked as a research assistant at the Edward Grey Institute, was advised by the ornithologist David Lack, and was influenced by the ethologist Niko Tinbergen. In 1950 he returned to the University of Cambridge to become the initial Curator of the Ornithological Field Station, designed by William H. Thorpe to integrate studies on instinct and learning (Hinde 1987). The station was established at Madingley, three miles from Cambridge, under the auspices of the Department of Zoology. Later it became the Sub-Department of Animal Behaviour, where from 1970 onwards it housed the Medical Research Council Unit on the Development and Integration of Behaviour, a focus of primate research. Hinde continued to work there as Honorary Director until his retirement in 1989. From 1950 to 1989 Hinde also taught in the Department of Zoology at the University of Cambridge, where in 1963 he became the Royal Society Research Professor of Zoology. In 1989 he retired from teaching and began a 5-year term as Master of St. John's College.

During his career, including almost three decades following retirement, Hinde wrote more than 15 books and 300 scientific articles and edited or co-edited a further 19 books. He won awards or medals in ethology, primatology, developmental psychology, social psychology, psychiatry, and anthropology, including becoming a Fellow of the Royal Society in 1974 and a Foreign Associate of the USA National Academy of Sciences in 1978. His students included Richard Andrew, Neil Chalmers, Dorothy Cheney, Tim Clutton-Brock, John Crook, Dian Fossey, Jane Goodall, Sandy Harcourt, Phyllis Lee, Patrick McGinnis, Robert Seyfarth, Kelly Stewart, and Richard Wrangham (Kelley and Sussman 2007).

Hinde's doctoral dissertation was a year-long study of the behavior of wild great tits (*Parus major*) in Marley Wood (Hinde 1952). He followed with a series of studies analyzing the causation of behavior, including courtship and predator-mobbing in captive birds (chaffinches *Fringilla coelebs* and greenfinches *Chloris chloris*), at the same time becoming increasingly involved in behavioral endocrinology. During this early work, Hinde was concerned with integrating the concepts of instinct, as analyzed by Konrad Lorenz and Niko Tinbergen, and learning and development, as emphasized by Daniel Lehrman. This effort culminated in his path-breaking 1966 textbook, *Animal Behaviour: A Synthesis of Ethology and Comparative Psychology* (second edition 1970).

An important shift in Hinde's research interests began in 1953 after the ethologist Konrad Lorenz heard him distinguish a series of processes involved in the waning of the mobbing reactions of chaffinches to owls. Lorenz was deeply impressed and recommended Hinde's work to the developmental psychiatrist John Bowlby. In February 1954, Bowlby and Hinde talked together for the first time at a scientific meeting on ethology and psychiatry organized by the Royal Medico-Psychological Association (RMPA) in London (van der Horst et al. 2007). Their relationship became one of strong mutual influence. Bowlby credited Hinde as a crucial source of advice in his scientific development of attachment

theory, including asking Hinde to comment on his draft manuscripts. Hinde became fascinated with the potential to use behavioral studies to solve human problems. In 1959, in order to study the effects of separation of infants from their mothers, he added a colony of rhesus monkeys to the Madingley field station. Hinde's monkey studies, conducted with Yvette Spencer-Booth, Lynne Davies and others, led him to an increasing focus on human behavior and research on children, represented by his 1974 book *Biological Bases of Human Social Behaviour* (McGraw Hill, New York). It also led him to becoming the advisor for a series of primatologists working in the wild, beginning with Jane Goodall in the 1960s. Hinde helped to systematize the study of primates by insisting on rigorous methods. Among other contributions, he developed the Hinde index, which operationalized the responsibility taken by individuals for maintaining proximity within a dyadic relationship, and he provided an empirical concept of social relationships as the nature, frequency, and patterning of social interactions.

After retiring from teaching in 1989, Hinde was an active Emeritus Royal Society Research Professor based in St. John's College, Cambridge. He devoted much of his writing to papers and books on eliminating the causes of war, including *War No More* (Hinde and Rotblat 2003). He was Chair and President of the British Pugwash Group and President of the Movement for the Abolition of War. He was convinced that "changing the popular view of war as heroic, inevitable, or a solution to disputes, must be an important strategy for peace."

Definition

Professor of psychology and evolutionary psychologist, at the University of Pennsylvania.

Introduction

Dr. Robert Kurzban, Ph.D., is a professor of psychology at the University of Pennsylvania who specializes in evolutionary psychology. He attended graduate school at the University of California, Santa Barbara (UCSB), where he studied under evolutionary psychologists Dr. Leda Cosmides and Dr. John Tooby. Kurzban earned his Ph.D. from UCSB in 1998. After earning his Ph.D., Kurzban accepted a postdoctoral fellowship in the Economic Science Laboratory at the University of Arizona (1998–2000) followed by a postdoctoral fellowship in the Department of Anthropology at the University of California, Los Angeles (2000–2002). He joined the Department of Psychology at the University of Pennsylvania in 2002. Shortly after joining the University of Pennsylvania, he founded the Pennsylvania Laboratory for Experimental Evolutionary Psychology. He has also served as a Visiting Research Associate at the Economic Science Institute at Chapman University and the Rasmuson Chair of Economics at the University of Alaska Anchorage.

Career

Dr. Kurzban is an evolutionary psychologist who has researched many facets of human behavior but is arguably known best for his work on the modularity of the mind. Dr. Kurzban's work has posited that different behaviors may be controlled by different mental mechanisms (Kurzban 2010). At times, these mechanisms may have conflicting goals, which may result in internal decision-making conflicts for individuals. For example, one mechanism may motivate an individual to eat some cookies, while a second mechanism may motivate that same individual to be healthy and therefore eat a salad instead of the cookies. The stronger mechanism will “win” this conflict, which leads the individual to engage in the behavior of that mechanism (i.e., either the individual will adhere to the first mechanism and therefore eat the cookies, or they will adhere to the second mechanism and eat a salad). This modularity may also give the illusion of free will, as individuals believe they are making a free choice when they are adhering to the stronger mechanism. In 2010, Kurzban published a book titled *Why Everyone (Else) Is a Hypocrite*, which focuses on this theory of modularity within the mind.

In 2014, Dr. Kurzban published a second book – coauthored with Jason Weeden – on self-interest in politics. The book, titled *The Hidden Agenda of the Political Mind: How Self-Interest Shapes our Opinions and Why We Won't Admit It*, covers a range of controversial and politically charged topics such as the legalization of marijuana, gay marriage, abortion, affirmative action, and many others. The books take a nonpartisan stance and illustrate how and why people take the political stances they do, as well as how and why people – both liberal and conservative – believe their political stance is the just and sensible viewpoint, while their opponents' political stance is ignorant (Weeden and Kurzban 2014).

Conclusion

Kurzban is an active writer who continues to publish new psychological research. Besides his

two popular press books mentioned above, Kurzban is the editor of five academic books on evolutionary psychology (see references), and he has published a combined total of over 100 peer-reviewed articles, book chapters, and book reviews. He has also consistently written blogs covering a range of topics in evolutionary psychology and popular culture and serves on numerous editorial boards for different peer-reviewed evolutionary psychology journals. As of 2016, he is the editor in chief of *Evolution and Human Behavior* – a peer-reviewed scientific journal that publishes research in the field of evolutionary psychology and the official journal of the Human Behavior and Evolution Society. He is also the editor of five new volumes of texts covering a wide range of topics within evolutionary psychology (Kurzban, 2016a, b, c, d, e)

Dynamic operation of several cognitive mechanisms adapted throughout evolution to solve socialization problems.

Introduction

The majority of other species' individuals only cooperate for common goals when they are genetically close. Humans commonly cooperate with one another for the common good. This happens at a level from individual–individual interactions such as mother–child relationships or friendship, to individual–group interactions, for example, people who sacrifice their lives in defense of a nation in a war. These behaviors can be explained from some cognitive mechanisms adapted by the evolution of the human species (Kurzban and Leary 2001; Kurzban and Neuberg 2005; Kurzban et al. 2015).

Cognitive Mechanisms and Group Processes

The interactions among individuals to form and maintain groups are limited by the costs of establishing a social network, and choosing a

social interaction imply excludes some others (Kurzban and Neuberg 2005). Therefore, this choice represents an adaptive problem that would have favored cognitive mechanisms designed to make good decisions about social interaction. Group processes involve some opportunities and costs. These opportunities can include benefits such as parental investment and cooperation to achieve mutual goals. Besides, the costs can include direct conflict and violence, competition for scarce resources, transmission of infectious diseases, and so on.

Kurzban and many collaborators have investigated computational mechanisms in humans designed to group processes. These researches involve different adaptation of cognitive mechanisms that make up the dynamics of human group relations. First, Kurzban contributed to the evolutionary game theory, researching individual differences in group cooperation processes through experimental methods, such as social dilemma game and public goods game (Kurzban and Houser 2001; Houser and Kurzban 2002). For example, investigating the influence of individual differences on group contexts, Kurzban and Houser (2005) reinforced the evidences that the reciprocity is an important motivator in group contexts because groups composed of mostly cooperative types enjoyed improved group cooperation and tend to earn more. Second, their researches demonstrated that the human cognitive mechanisms explain relationships of cooperation or competition and the management of ingroup and outgroup engagement. Concomitantly, many others process directly or indirectly involved in these phenomena were researched, such as morality (DeScioli and Kurzban 2009a, 2013), stigmatization (Kurzban and Leary 2001), altruism (Kurzban et al. 2015), social exclusion, prejudice and discrimination (Kurzban and Neuberg 2005), alliance and friendship (DeScioli and Kurzban 2009b), revenge and forgiveness (McCullough et al. 2013), among others.

As an example of these researches, DeScioli and Kurzban (2009a) realized an adaptationist analysis of morality, highlighting three evolutionary mysteries of moral condemnation: third-party judgment, moralistic punishment, and moral

impartiality, concluding that these processes are performed by different cognitive mechanisms. As a possible solution to explain a variety of mysterious moral phenomena, DeScioli and Kurzban (2013) proposes that moral condemnation functions to guide of choosing sides in conflicts. Thus, moral cognition would be designed to manage two coping strategies when conflicts occur: choice based on the high status of the disputant or on the preexisting relationships. The decision comes through the implementation of a dynamic coordination strategy in which bystanders coordinate the choice of side by focusing on the contestants' actions rather than their identities. These researches proposed the dynamic coordination theory based on mind computational theory. It regards the human mind as an advanced computational control system. Therefore, moral cognition, as part of these systems, is a cognitive mechanism designed to execute highly sophisticated processes in the computations and strategies of many our social interactions and particular reflections.

Finally, DeScioli and Kurzban (2009b) proposes human friendship would be based on cognitive mechanisms designed to bring together support groups for potential conflicts. Grounded on the computational theory of games, the alliance hypothesis for human friendship recognizes that human friendship results from a system of alliance similar to the alliance between countries, not based on proximity or exchange of benefits. Thus, the friendship would occur through a self-reinforcing process initiated when individuals value each other because their partners value them. All researches presented indicate the existence of various systems operating in the same organism dynamically; all these processes derive from a set of cognitive mechanisms adaptations throughout evolution to solve problems related to socialization.

Conclusion

Kurzban and scholars suggest that there are different adaptations for the different types of sociality. Thus, the human cognitive adaptations will

probably consist of a set of shared systems designed for the personal choice of interaction partners, as well as the entry and stay in groups, and also for group processes of cooperation and competition (Kurzban and Leary 2001; Kurzban and Neuberg 2005; Kurzban et al. 2015). Human beings have cognitive mechanisms adapted to discriminatory sociality and have psychological mechanisms designed to maintain and maximize the benefits and to limit and minimize the costs derived from it (Kurzban and Leary 2001; Kurzban and Houser 2005). Advances in cognitive mechanisms and group processes researches have led to new challenges on human cooperation's studies. Issues such as development, punishment, and parents and offspring demand special attention (Kurzban et al. 2015).

Definition

One of the most influential contributors to modern evolutionary theory, Trivers' work utilizes

selection acting at the level of the gene to understand the adaptive function of complex human behaviors such as cooperation, conflict, self-deception, homosexuality, and the evolution of morality.

Introduction

Robert Trivers is undoubtedly one of the most important and influential thinkers in modern history. His work inspired and revolutionized entire disciplines including sociobiology, evolutionary psychology, behavioral ecology, evolutionary genetics, and economics. His series of papers published in the early 1970s resulted in an explosion of empirical work on a diversity of species from insects to humans. Trivers introduced evolutionary theory to economic thinking, by embracing selection acting at the level of the gene; he sought to understand the adaptive function of behavior as well as the constant selective pressures that result in increased efficiencies. Trivers recognized the power of viewing social behavior as a co-evolutionary struggle between constant conflict and cooperation – within the individual, relationships, and groups. Trivers presented an eloquent and simple underlying logic that explains the complexity of social interactions in terms of the partial overlap of genetic interests between and within different groups of organisms.

Early Life and Education 1943–1966

Robert Ludlow Trivers was born on February 19, 1943, in Washington, D.C., the second of seven children of Mildred Reynolds Trivers, an accomplished poet, and Howard Trivers, a diplomat and philosopher. Throughout his life, Trivers' academic interests have been varied and intensely studied, at 12 he became obsessed with astronomy, and by 13 he had moved on to math and mastered differential calculus in 2 months using only textbooks. After graduating from Phillips Academy in Andover Massachusetts, Trivers enrolled at Harvard University in the fall of 1961 as a math major. His interest in math soon waned

and he decided to focus on becoming a lawyer to fight for justice and equal rights. In 1965, Trivers graduated from Harvard with a degree in history and, after recovering from the first in a series of mental breakdowns, found a job writing fifth grade science textbooks, which included teaching evolution. Having never taken a course in biology nor any particular interest in or experience with animals, Trivers was assigned Bill Drury, an ornithologist to mentor him.

Drury's wealth of knowledge in animal behavior and ecology, and passion for the emerging field of evolutionary biology, exposed Trivers to the principles of evolutionary theory and invaluable fieldwork experience. Trivers describes the moment he comprehended the power of viewing the world from the perspective of natural selection acting at the level of individual genes as "I felt a sense of religious awe (Trivers 2002)."

Academic Career at Harvard 1966–1978

In the spring of 1966, Bill Drury introduced Trivers to Ernst Mayr who encouraged him to enroll at Harvard to earn a PhD in evolutionary biology. Observing pigeon behavior on the roof of his Cambridge apartment led Trivers to describe behavior we now refer to as extra pair copulations, mate guarding, male-male aggression, and sexual coercion – all present in what was thought to be a relatively conflict-free "monogamous" mating system. He began to think of these interactions as strategies, with economic costs and benefits measured in genetic contribution to the next generation, based on context-specific ecological conditions.

Trivers conducted his dissertation research on *Anolis* lizards in Jamaica under Harvard's curator of herpetology, Ernest Williams. Trivers was one of the first to study how a single parameter (body size) affected reproductive success differently in the two sexes in nature (Trivers 1976).

Trivers spent the late 1960s until 1978 at Harvard, first as a graduate student, then as a postdoc under Irvan DeVore, and eventually as an instructor, assistant professor, and associate professor. He married his first wife Lorna Staple in 1974.

During this time, he published a series of remarkable papers that revolutionized the field and evolutionary biology and generated entire fields of inquiry on social behavior.

Reciprocal Altruism

After attending a talk by Richard Lewontin at Harvard in the spring of 1969, Trivers realized that theoretical ecology was not something he would enjoy. He decided to put his intellectual energy into solving important questions in the field that had yet to be resolved. He set his sights on reciprocal altruism. Darwin's theory of evolution by natural selection was based on the premise that individual organisms are expected to engage in behaviors that directly increase survival and the probability of their genes being passed on to future generations. The presence of altruistic behavior in nature was a puzzle that Darwin had been unable to solve. Unrelated individuals engaging in behavior, where the actor incurs a cost and the recipient a benefit (in terms of reproductive success), appear counterintuitive to Darwin's theory. In 1964, WD Hamilton laid out logic for altruism being selected for in related individuals, based on kin selection and inclusive fitness theory. Hamilton utilized evolutionary logic acting at the level of the gene and mathematical modeling to explain how altruistic behavior could have evolved within populations based on their degree of relatedness (Hamilton 1964). Trivers introduced the concept of reciprocity to explain how altruism between unrelated individuals could have evolved based on economic principles. He created a testable hypothesis regarding repeated interactions between unrelated individuals and identified the ecological conditions that would favor the evolution of reciprocal altruism as an adaptive strategy for individuals to cooperate in order to increase individual survival and reproductive success. Trivers argued that repeated opportunities to engage in altruistic behaviors with the same individuals, in order to build up reciprocal relationships and maximize long-term benefits, were a key factor in the evolution of reciprocal altruism. Trivers predicted that

biological parameters such as long life spans, low dispersal rates, a need to interact for mutual dependence, and parental care would allow for many repeated interactions between individuals over a lifetime. The promise of delayed return over time confers benefits to individuals who participate by conforming to rules of the social system based on reciprocity – low cost to actor and high benefit to recipient. Over time, Trivers argued, these conditions select for the evolution of cooperation. One issue Trivers kept coming back to was cheaters – individuals who take benefits but do not incur costs, by not reciprocating. Under specific circumstances, this would be adaptive. Trivers argued that given the unstable nature of the system, evolution would rapidly favor complex psychological mechanisms in individuals to regulate both their altruistic and cheating tendencies. He viewed relationships between individuals as complicated interactions involving costs and benefits associated with conflict and cooperation determined by patterns of overlap and nonoverlap of long-term genetic interests. Trivers argued that the evolution of reciprocal altruism led to the development of complex human emotions to maximize survival and reproductive success within a wide variety of social relationships. Emotions such as friendship, loyalty, fairness, justice, gratitude, sympathy, empathy, moralistic aggression, guilt, regret, remorse, and compassion are examples (Trivers 1971).

Trivers' work on reciprocal altruism led to the evolution of entire disciplines including economic game theory. EO Wilson had encouraged Trivers to expand his theory in mathematical terms; WD Hamilton and Axelrod accomplished this in 1981 in the development of an evolutionary stable rule of action, elegant in its simplicity – tit for tat.

Parental Investment Theory 1972

After reciprocal altruism was published, unlike most academics that may have chosen to build a career around this important topic, Trivers immediately moved on to a subject where he felt there was progress to be made – sexual selection. While Darwin had identified the two basic types of

sexual selection, male-male competition and female choice, Trivers felt that Darwin's treatment lacked a general framework within which important variables could be related. At the insistence of Ernst Mayr, Trivers read Bateman (1948) in *Heredity* and rediscovered the concept variance in reproductive success analyzed by sex. Trivers also reviewed behavioral data on sex role reversed species from George Williams and developed a theory to explain details of the male-female relationship in terms of the amount each sex invested in individual offspring. Trivers formulated an objective and unbiased system for thinking about evolution of the two sexes that emphasizes equality of parents – each receiving 50% genetic representation in offspring. His theory was sex-blind, based on parental investment strategies not biological sex and could be applied everywhere. This theoretical framework could be used to explain a wide range of sexually dimorphic features and behaviors, from body size and shape to sex differences in complex psychological behaviors such as sexual jealousy and homicide (Trivers 1972).

Trivers-Willard Effect 1973

In 1970, Trivers was a teaching assistant in Irven DeVore's Primate Behavior course when he met Dan Willard, a graduate student in mathematics. After attending his lectures on sex ratio at birth and the evolutionary logic of mate choice, Willard approached Trivers with an interesting question – wouldn't it make sense for humans to adjust the sex ratio of their offspring based on socioeconomic status? Fleshed out and published in 1973, the theory was simple and based on return on investment based on gender of offspring, dependent on maternal condition and differences in potential reproductive success in offspring by sex (Trivers 2002). The theory predicted in species with extreme variance in reproductive success between males (e.g., where a few males father the vast majority of offspring and most males father none); females of low rank or in poor condition should invest more in daughters, while dominant females with access to plentiful resources should invest more in sons. In most

species, the difference in reproductive output between females is much less variable than males, where each fertile female produces on average the same overall number of offspring. Females in good condition benefit in terms of inclusive fitness by investing in sons who have a better chance of becoming dominant and more often chosen as a mate, resulting in a much larger payoff for her investment in terms of potential reproductive success compared to daughters whose RS is less variable based on dominance and condition. Empirical evidence from mammals such as red deer and human populations supports the model. In human societies, because daughters tend to marry up the socioeconomic ladder and males do not, parental investment in daughters is favored at the lower end, where males often remain unable to afford mates and therefore have decreased prospects of obtaining RS. Male offspring born into high socioeconomic status have access to resources and can often afford multiple mates, therefore exponentially increasing the number of potential offspring and hence reproductive success (Trivers and Willard 1973).

Parent-Offspring Conflict 1974

In early 1971, Trivers began to develop a biological theory of the family based on natural selection. He determined that degree of relatedness (r) was the key parameter and decided to focus on the parent-offspring relationship. Trivers viewed the relationship in economic terms as a competing series of interactions involving cooperation and conflict based on overlapping genetic interests resulting in conflict over parental investment. Parents share 50% of their genes with each individual offspring ($r = 0.5$) and should therefore invest in each equally. Each offspring is related to itself by $r = 1$ but to the parent by $r = 0.5$, resulting in the offspring being selected to desire to continue extracting parental investment longer than the parent is selected to continue providing it.

Trivers utilized weaning conflict to mathematically model how parent-offspring conflict over length of the period of parental investment manifests, including specific behavioral tendencies that

would result in both parent and offspring in order to maximize their own individual RS (Trivers 1974). This line of reasoning eventually led Trivers to pursue conflict within the individual at the level of the gene via maternal and paternal imprinting and other forms of intergenomic conflict (Trivers 1995, 1997; Trivers Burt 1999).

Haplodiploidy and the Evolution of Social Insects

Irv DeVore arranged for Trivers to work as an anthropology instructor at Harvard in 1971. After lecturing on Hamilton's kinship theory (1974), Trivers decided to apply the logic of Hamilton's kinship and Fisher's sex ratio theory to understand the evolution of haplodiploidy in social insects. In the Hymenoptera (ants, bees, and wasps), unfertilized eggs develop into males and have only one set of chromosomes (haploid) and fertilized eggs are female (diploid), the majority of which are nonreproductives. Colonies in these species usually have a single reproductive queen and castes of nonreproductives that forgo reproducing themselves and instead invest in raising the offspring of the queen. This system is referred to eusocial and is relatively rare in nature, yet common within the Hymenoptera. Trivers was interested in developing the evolutionary logic explaining the complex interactions between the varying degrees of relatedness of individuals, overall sex ratio, and ratio of investment bias in eusocial colonies (Trivers and Hare 1976).

With the help of EO Wilson and Bert Holldobler, Trivers tested his hypothesis in over 20 species of ants and showed that once eusocial colonies appeared, the ratio of investment should be biased toward females and stabilize at a sex ratio of one male to three females.

Deceit and Self-Deception

Trivers was conscious of self-deception from an early age and recognized the pervasive and confounding use of deception in humans. Some

examples included biblical passages, the pervasive practice of purposefully misrepresenting prices (e.g., \$4.99), American history, and politics. After learning evolutionary biology, the mechanisms of self-deception appeared counter-intuitive to Trivers. After observing intense psychological warfare in baboons while in East Africa with Irv DeVore in 1972, it became clear to Trivers that the complex social nature of humans could easily select for self-deception because it allows for better deception of others. While working on parent-offspring conflict, Trivers' thoughts on the topic began to coalesce as he hypothesized that parents might be selected to induce self-deception in offspring to alter their behavior in ways that disproportionately benefit the genetic interests of the parent. This began a 40-year process of developing a cohesive theory on the evolution of deceit and self-deception (Trivers 1985, 1991, 2002, 2011).

University of California, Santa Cruz, 1978–1994

After being overlooked for tenure at Harvard, Trivers moved his family west to the University of California at Santa Cruz in 1978. Here he would raise his four young children, meet Huey P. Newton, and become a member of the Black Panther Party. He continued his exploration of self-deception, coauthoring a paper in 1982 with Huey Newton on the crash of Air Florida Flight 90. Cockpit voice recordings were analyzed to demonstrate the real cost of self-deception – an impaired ability to deal with reality (Trivers and Newton 1982). In 1991, Trivers formally presented the evolutionary logic for deceit and self-deception, exploring the connection between communication and consciousness (Trivers 1991).

Social Evolution 1985

In 1985, Trivers' long-awaited textbook on evolutionary social theory was published. It was

written for both general readers with no background in evolutionary theory and introductory undergraduate college courses in anthropology, animal behavior, or related disciplines. The book began with chapters that systematically laid out the theory of evolution by natural selection and basic genetics. The heart of the book introduced an interconnected body of theory and supporting evidence on the principles underlying social evolution including kinship, parent-offspring relationships, reproductive altruism, sexual selection, sex ratio, and the evolution of sexual reproduction. The final chapters covered social interactions in general, such as the evolution of cooperation and deceit and self-deception (Trivers 1985).

Mate Choice

Trivers viewed mate choice as an area ripe for investigation. After finishing his work on parental investment and sexual selection, he felt strongly that there needed to be a theory of mate choice based on genetic quality. He began in earnest in 1977 to solve this question and addressed it in 1985 in *Social Evolution* where he suggested that there was sexual selection pressure acting on females resulting in female-biased female choice (Trivers 1985). Trivers argued that this had been a neglected form of female choice but that it may be important in nature. Since the limiting reproductive factor for any population is fertile females, the species that improves daughters would have a competitive advantage. Collaborating with Jon Seger, they published a paper on asymmetry in the evolution of female mating preferences in 1986 using population genetic modeling to demonstrate that a female choice gene harming daughters was inhibited by its spread compared to female choice harming sons. This was the first work to explicitly show how female choice could have evolved to place special emphasis on traits that promote female fitness. Trivers views this as important work that has gone relatively unnoticed and an area still ripe for further research (Seger and Trivers 1986).

Fluctuating Asymmetry

In 1990, WD Hamilton gave a talk at UC Santa Cruz. Trivers asked him what was new in sexual selection and Hamilton replied “fluctuating asymmetry (FA).” Trivers interest in FA deepened after reading work on mate preferences and symmetry in birds and discoveries on correlates of fluctuating asymmetry in scorpion flies. FA refers to small deviations from perfect symmetry ($L-R = 0$) that fluctuate around zero. Levels of FA are measures of developmental stability and genetic quality. There was already a significant literature from biology with associations between FA and mate choice, reproductive success, body size, and fighting ability (Trivers 2002).

Rutgers University 1994–2017

Having divorced his first wife in 1988, Trivers moved back east in 1994 to teach in the ecology and evolution and anthropology departments at Rutgers University and be closer to his children. He remarried in 1997 to Debra Dixon and together they had a son in 1999. They divorced in 2004.

In 1994, Trivers coauthored a review paper on the science of symmetry in biology with coauthor Michal Polak (Polak and Trivers 1994). Trivers recognized the power of having an observable measure of genetic quality. Symmetry was not only easy to measure but had become recognized as a major variable in the study of humans including mate choice and attractiveness preferences. In 1996, Trivers led an international team of researchers including Devandra Singh, Randy Thornhill, and John Manning to Jamaica where they collected behavioral data and measured fluctuating asymmetry, waist-to-hip ratio (WHR), and second to the fourth digit ratio (2D:4D) on 285 Jamaican school children. Some initial findings revealed boys were more symmetrical than girls; Jamaican children were more symmetrical than European children; symmetry decreases as children age; the lower body is more symmetrical than the upper body; symmetry in one feature may

correlate with some behavioral traits, while others do not; and boys with symmetrical lower bodies were more aggressive (Trivers et al. 1999). Data was also collected from the subjects' mothers on 2D:4D and WHR, leading to the discovery by John Manning that 2D:4D ratio is positively correlated with the number of offspring in females, mothers with higher WHR gave birth to more sons, and low 2D:4D is associated with left handedness (Manning et al. 2000a, b). The project has resulted in numerous publications on topics including the ultimatum game, FA and running speed, mate choice, and 2D:4D (Trivers et al. 2004, 2013a, b). The initial subjects have been followed for over 20 years and are periodically remeasured, providing valuable longitudinal data on fluctuating asymmetry, reproductive success, and mortality (Trivers 2002).

Genetics

After completing *Social Evolution*, Trivers began pursuing his interest in the evolutionary dynamics of within-individual conflict in earnest. He underestimated the vast and complicated nature of genetics but found willing collaborators in Austin Burt and David Haig. Trivers coauthored several papers on B chromosomes in plants and insects, selfish DNA and breeding systems in flowering plants, the logic of kinship theory applied to genomic imprinting, and the genetic basis of intrapsychic conflict (Burt and Trivers 1998; Trivers et al. 2004). After 15 years of research on genetic conflict within various organisms, Trivers and Burt published a comprehensive book on the topic in 2006, *Genes in Conflict: The Biology of Selfish Genetic Elements* (Burt and Trivers 2006).

Self-Deception

In 2011, Trivers published a book on deceit and self-deception. It was a culmination of a lifetime of personal observations and extensive research and delivered a general theory of deceit and self-

deception based on evolutionary logic. In typical Trivers fashion, the book takes a comprehensive, interdisciplinary, and functional approach, providing supporting evidence from neurophysiology, immunology, evolutionary genetics, sexuality and reproduction, and psychology. Trivers uses his theoretical framework to examine self-deception in real life from the role it plays in space disasters and the stock market to the complex way it manifests in humans from confirmation bias and religious belief in individuals to genocide and war between groups (Trivers 2011).

Current Research Interests

Trivers, along with Bernhard Fink and John Manning, published a series of papers on symmetry, 2D:4D, and FA in elite Jamaican sprinters (Trivers et al. 2013b, 2014). Following up on his research on self-deception, Trivers collaborated with Bill von Hippel on the aging positivity effects and function of the immune system (Kaloerinos et al. 2014). He is still interested in trying to provide evolutionary logic to explain behavioral phenomenon that appear to contradict expectations. Some areas he intends to make progress on include homosexuality, where same-sex attraction decreases individual reproductive success, honor killings, where family members kill closely related individuals in order to restore honor to the family, and the evolutionary genetics involved in cancer.

Honors and Awards

Trivers has been recognized and honored for his contributions to science by diverse organizations around the world. His work was recognized by *Time Magazine* when he was featured as one of the top 100 thinkers of the twentieth century. He is an honorary distinguished fellow at the University of the West Indies, received a regents fellowship at the Smithsonian Institution, has been a fellow at the Institute of Advanced Studies in Berlin, received the distinguished Animal Behaviorist

Award from the Animal Behavior Society, is a member of the American Academy of Arts and Sciences, and received fellowships from the John Simon Guggenheim Foundation and Smithkline-Beecham. In 2007, Trivers was awarded the prestigious 25th Crafoord Prize by the Royal Swedish Academy of Sciences for his seminal contribution to understanding the evolution of complex social behaviors by introducing evolutionary logic to view life in terms of selection acting at the level of the gene in a series of conflicting and cooperative strategies.

Wild Life

In 2015, Trivers' autobiography *Wild Life: Adventures of an Evolutionary Biologist* was published. In it he describes his unconventional life, from literally stumbling upon evolutionary theory to death-defying adventures in the field; Trivers reflects on his life with unusual candor and brutal honesty. A full-length feature documentary *Wild Life* is scheduled for release in 2017 (Trivers 2015).

Conclusion

Robert Trivers has had a profound influence on our understanding of the human condition. His unique ability to master literature and make connections between the economics of efficiency based on degrees of relatedness and complex social behavior has had a profound effect across multiple disciplines. By taking a functional approach to genes and behavior, Trivers' work has allowed for a depth and breadth of knowledge on the biology of social behavior that has enhanced our ability to better comprehend life itself.

Definition

Robin Baker and Mark Bellis are two British researchers who carried out a series of pioneering and controversial studies into human sperm competition and female orgasm in the late 1980s and early 1990s.

Introduction

Robin R. Baker was an evolutionary ecologist at the University of Manchester, where he was best known for his work on the evolution of reproductive strategies in humans and other animals. In the late 1980s and early 1990s, he and his student Mark A. Bellis carried out a series of groundbreaking studies on intrasexual competition in humans. The chief results from this research were published in four prominent papers in the journal *Animal Behaviour* (Baker and Bellis 1989, 1990, 1993a, b) and in a 1995 book (Baker and Bellis 1995). Although their studies received criticism (Schilthuizen 2014; see below), these five publications jointly have been cited in the scientific literature more than 1,500 times.

Baker and Bellis Studies

Using data from women interviewed in three UK cities, Baker and Bellis first showed that human “double mating” (i.e., copulation while fertile sperm from a previous, different partner is still present in the woman’s reproductive system)

takes place at a frequency of c. 0.1 % of all copulations (Baker and Bellis 1989). This is a rate high enough to allow the evolution of competitive traits in ejaculates. They then collected ejaculates (resulting from either copulation or masturbation) from volunteers and counted sperm content. They discovered that the proportion of time a couple had been separated since their previous copulation (and, hence, the likelihood of male intrasexual competition) was a strong predictor for the number of sperm in a copulation-derived ejaculate. Ejaculates collected after masturbation, however, did not show such a relationship. This indicated that, as theory predicted, human males are able to adjust the competitive ability of their ejaculate in response to the likelihood of sperm competition.

In a separate study, based on a large questionnaire returned by over 3,700 female readers of the magazine *Company*, Baker and Bellis showed that the women's sexual activity patterns also played a role in this: extra-pair copulations (the ones that would potentially generate such double matings) took place at peak fertility more often than expected by chance (Baker and Bellis 1990).

In 1993, Baker and Bellis published two back-to-back papers (Baker and Bellis 1993a, b) with a much larger analysis of the data from their *Company* questionnaire, as well as data from an experiment with an extended set of volunteers: not only men who were asked to return condoms with copulation/masturbation ejaculates but also women who were asked to collect "flowback," the semen that emerges from the vagina after unprotected sex – often interpreted as a form of sperm dumping (Schilthuisen 2014). In total, the study involved 278 ejaculates. In addition, the volunteer couples filled out detailed questionnaires on their sexual activities during the experimental period.

These larger analyses showed several things. First, they confirmed the earlier results that their male volunteers ejaculated larger numbers of sperm during copulation (but not during masturbation) if they had been separated from their partners for longer. Moreover, the numbers of sperm that men ejaculated were consistent with a "topping-up" model, where men manage their

ejaculations such that an optimal number of sperm cells are always present in the reproductive system of their partners.

Second, they showed that, although the concentration of sperm cells in an in-copula ejaculate decreased if there had been a recent masturbation, this did not negatively affect the number of sperm retained by the woman. Baker and Bellis interpreted this as an indication that masturbation serves to prevent the accumulation of senescent sperm cells and thus to maintain the quality and fitness of the next in-copula ejaculate.

Finally, they showed that there is great variability in the amount of flowback, ranging from full retention of the entire ejaculate to its full ejection. More importantly, the amount of retained sperm cells was largely dependent on female orgasm. Without orgasm or if orgasm took place more than a minute before male ejaculation, few sperm cells were retained. Baker and Bellis interpreted this as a sign that female orgasm serves a role in cryptic female choice, by enhancing (perhaps via the negative pressure created inside the uterus during climactic spasms; Baker and Bellis 1993b; Schilthuisen 2014) the uptake of ejaculated sperm.

Conclusion

The publications by Baker and Bellis form a classic set of studies, since they were the first to test, in an experimental setting, hypotheses about sperm competition in humans. However, they were also criticized because of small sample sizes, questionable methodologies, and overinterpretation of the results. One claim specifically, namely, that some sperm cells ("kamikaze sperm") in human ejaculates serve to physically interfere with competitors' sperm cells in double-mating situations, could not be replicated later (Moore et al. 1999). In 1996, Baker moved out of academia and became a free-lance author of popular science books (of which the 1996 *Sperm Wars* is the best known; Baker 1996) and novels, in which he continued to use the intrasexual competition themes of his research work. He was attacked by his academic colleagues for promulgating

unsubstantiated evolutionary interpretations of various human sexual behaviors in these books.

Since retiring from academia, Robin Baker has been a science communicator and novelist. Mark Bellis is currently Director of Policy, Research and International Development at Public Health Wales.

Human sperm competition: the competition to fertilize a woman's egg that takes place inside a woman between sperm from two or more different men.

Introduction

From 1962–1970, Robin Baker studied zoology at the University of Bristol, UK. One of his contemporaries, both as an undergraduate and postgraduate, was Geoffrey Parker who, around 1965, was the first person to recognize the phenomenon of sperm competition. Parker's focus was on insects, but from the beginning, according to Baker (2015; p. iv), Parker envisaged a wider relevance for his theory. During the winter of 1965–1966, the pair shared an apartment, and there, Baker writes, they would sit “talking about sex – as postgraduates do.” Mainly, their conversations revolved around dung flies, but from time to time, they mused

Robin Baker has retired

over whether sperm competition might also occur in humans. Their conclusion was always the same: maybe it did, but study would be impossible. A further 20 years were to pass before Baker revised that conclusion.

Parker eventually published his groundbreaking ideas for insects in 1970 (Parker 1970). Slowly at first, then faster, sperm competition became recognized as a major evolutionary force for a range of animals. The first collection of papers on the subject was organized by Robert Smith, University of Arizona, USA, who dared to end the volume by proposing that sperm competition really could have been an evolutionary force on humans (Smith 1984).

A year after this collection of papers was published, a chance meeting triggered the transformation of Smith's speculations into an experimental investigation. Robin Baker had by then been a lecturer in zoology at the University of Manchester, UK, for a decade. In Baker's (2015) account of those years, he describes (p. viii) how in his Behavioral Ecology lectures he annually proclaimed that human sperm competition would be a "fantastic" subject area. "Totally impossible to study, of course," he would say, "unless one of you..." and he would wave his hand around the class "...can think of how it could be done." Baker had made that gesture and spoken those words 6 or 7 years in succession before a student came to his room to say that he thought he did know how it could be done. His name was Mark Bellis.

So began a 10-year collaboration that on the one hand developed the latent field of human sperm competition into a serious scientific study but, on the other, greatly divided academic opinion. To some, Baker and Bellis were "heroes" (Gowaty 1996) and their papers eventually "classic" (Shackelford and Pound 2006; p. xix). To others, their work was mere fantasy. According to Tim Birkhead (2000; p. 29), quoting the title of the 1992 cult film by GWR, "Robin Baker and Mark Bellis may see themselves as pioneers in the study of human sexuality, but ... the view of human sperm competition they have perpetuated is little more than sexual fantasy – phallus in wonderland."

The Collaborative Decade (1985–1995)

Kamikaze Sperm (1988)

Baker and Bellis's first publication (1988) was to be their most notorious. Entitled '*Kamikaze Sperm in Mammals?*', the paper hypothesized that not all sperm in mammalian ejaculates were present to fertilize eggs.

It had long been known that mammalian ejaculates, including those of humans, always contained a proportion of strangely shaped sperm. Head shape, for example, varied hugely, some being small, others large, and yet others pear shaped, cigar shaped, or simply oddly shaped. Some even had two heads or more. Tails varied too: short, bent, coiled, or double. The proportions differed consistently between species: in gorillas and humans, up to 40% of sperm could look very different from "normal," whereas in chimpanzees, the proportion was nearer 5%. Traditionally, such sperm had been interpreted as abnormalities: mistakes during sperm formation (Cohen 1977). Baker and Bellis (B&B, for short) suggested instead that they were adaptations to sperm competition. Some were even present specifically to die – a "kamikaze" role – a suggestion inspired by B&B's study of rats.

During mating, a male rat leaves a hard plug of coagulated semen in the female's vagina. This hinders mating by later males. The plugs are reinforced by the intertwined bodies of countless dead sperm (Baker and Bellis 1988) perhaps making them stronger and more difficult to remove. B&B proposed that such large-scale sacrifice of sperm could increase, not decrease, the plug producer's chances of fertilizing the female's eggs.

Although the "Kamikaze Sperm Hypothesis" was B&B's first joint publication, it was to remain a purely theoretical concept until their very last joint publication 7 years later. Only then did they formulate the hypothesis fully and provide experimental support.

Ejaculate Adjustment During Copulation (1989)

By the mid-1980s, Geoff Parker had produced a number of testable sperm competition hypotheses, one being that the greater the risk of sperm

competition, the more sperm a male should inseminate.

To test this prediction for humans, B&B began recruiting volunteer couples to collect ejaculates from copulation and masturbation during their normal sexual activity (using condoms) and to return these to the Manchester laboratory for analysis. A questionnaire was also completed for each ejaculate, one of the questions being the percentage of time the pair had spent together since their last copulation. Nobody had carried out such a study before.

B&B reasoned that the less time a pair spent together, the more likely was the female to mate with a different male between matings with her partner. They suggested, therefore, that percentage time together between copulations could be used as a proxy for risk of sperm competition. Their resulting prediction, based on Parker's hypothesis, was that the lower the percentage of time a couple had spent together since their last copulation, the more sperm the male should inseminate at the couple's next copulation. Such a trend should not be present for masturbatory ejaculates.

The paper eventually published (Baker and Bellis 1989), entitled "*Number of sperm in human ejaculates varies in accordance with sperm competition theory*," supported this prediction. Perhaps even more importantly, it provided the first demonstration that humans could be used to test the predictions of sperm competition theory.

Frequency of Human Sperm Competition (1989–1990)

Robert Smith (1984) listed a range of situations in which human sperm competition should occur: prostitution, group sex, gang rape, rape, and, top of the list, female infidelity. Figures existed for all of these activities, not only for the USA but also for Europe. None, however, could be converted into rates of sperm competition nor, more importantly, how many children were conceived as a result.

When a woman conceives to a man other than her recognized partner, it is said to be an example of extra-pair paternity. Traditionally, based on

little more than hearsay and anecdotes, medical students had been taught that the level of extra-pair paternity in modern society was around 10–15%. This was the figure still being quoted in medical textbooks when B&B began their collaboration. However, even this figure could not be used as a frequency for conception via sperm competition because not all cases of extra-pair paternity are the result of sperm competition.

In April 1989, in collaboration with the UK woman's magazine *Company*, B&B circulated a questionnaire nationwide which would enable them to calculate the figure needed. From nearly 4,000 replies, they separated out data for women being unfaithful "unprotected" by contraception during the fertile phase of their menstrual cycle. From these, they calculated that the proportion of UK children likely to be conceived via sperm competition was indeed likely to be of the order of 10% (Bellis and Baker 1990).

In order to make this calculation, an assumption had to be made about how long sperm stayed fertile once inside the female. Robert Smith (1984) had argued that for a woman to contain live sperm from two different men in her reproductive tract and to generate sperm competition, she would need to mate with a second male no more than 7–9 days after the first. B&B adopted a more conservative 5-day gap.

On the basis of a 10% figure for conception via sperm competition, B&B claimed that sperm competition had indeed been common enough through human evolution to exert a significant selective pressure on the shaping of human sexuality.

Female Promotion of Sperm Competition (1990)

Sperm competition theory focussed first on the behavior of males. However, as Robert Smith (1984) had noted, females could also gain benefits. If sperm competitiveness is heritable, females fertilized by the most competitive sperm will gain through the greater reproductive success of their sons. So, if a female is unable to judge ejaculate quality from a male's appearance, her best strategy is to promote sperm competition via *double matings* (matings that lead to a woman having

sperm from more than one male inside her reproductive tract) around times of peak fertility.

The *Company* dataset allowed B&B to test this hypothesis (Bellis and Baker 1990). Although female infidelity in general showed no pattern with respect to the menstrual cycle, double matings “unprotected” by contraception were most likely during the fertile phase. B&B concluded that women are most likely to promote sperm competition when the probability of conception is highest.

Ejaculate Adjustment During Copulation and the Function of Male Masturbation (1993)

Armed with their *Company* data plus further copulatory and masturbatory ejaculates collected by more couples, B&B were now in a position to use humans to test a much greater variety of hypotheses from Parker’s sperm competition theory (Baker and Bellis 1993a).

B&B began by providing evidence that the percentage of time couples spent together really was a good proxy for risk of sperm competition. They then demonstrated that from intercourse to intercourse, even individual males would adjust the number of sperm inseminated into a long-term partner according to the risk that she might contain sperm from another male. Another of Parker’s predictions, that males should inseminate more sperm into women of higher reproductive value, in B&B’s case larger women (within the normal healthy weight range), was also tested and supported. Finally, B&B evaluated the prediction that a male should optimize his partitioning of sperm across successive copulations with his long-term partner. In this last case, however, they rejected existing models in favor of their own “top-up” optimization model.

The 1993a paper was also notable because, for the first time, B&B cast doubts over an existing tenet of sperm competition theory. Most early predictions had assumed that the number of sperm inseminated is a trade-off between two opposing pressures: (1) risk that sperm may find themselves in competition with sperm from another male, favoring more sperm, and (2) the cost of sperm production, favoring fewer. However, for male mammals, B&B noted that this

trade-off ignores the apparent wastage from self-masturbation and spontaneous emission which runs counter to sperm cost being a critical factor.

The data presented in their 1993a paper showed that a recent (<72 h) masturbation did reduce the number of sperm inseminated at the next copulation but had no effect on the number retained (see section “**Female Orgasm (1993)**”) by the female. B&B concluded that male masturbation functions to increase mean sperm fitness by reducing sperm numbers. This in turn suggested that, in the absence of sperm competition, the probability of fertilization actually decreases if too many sperm are inseminated, a factor that B&B claimed could be more important than sperm cost in favoring male restraint over the number inseminated.

Female Orgasm (1993)

Three explanations for the female orgasm existed in the early 1990s: (1) it was functionless and, like nipples on males, existed only because its functional counterpart existed in the other sex; (2) it disinclined a woman to walk around after intercourse, thus reducing loss of the ejaculate; and (3) it sucked semen from the vagina into the uterus.

According to Baker (2015; p. ix), he and Mark Bellis had mused over the female orgasm from the beginning of their collaboration. Although believing it to be part of the sperm competition story, they were unable to see a role, the main problem being their suspicion that most female climaxes occurred outside of copulation.

The eventual “game changer,” Baker (2015; p. ix) writes, was a chance remark by a female collaborator who questioned why men should bother making fine adjustments to sperm number when so much of the ejaculate comes back out of the woman within the hour. She was immediately press-ganged into pioneering a collection technique for what B&B chose to call the “flowback,” thus beginning a whole new branch of study never attempted before.

In B&B’s eventual publication (Baker and Bellis 1993b), the flowback was transformed from a medically undesirable “sperm loss” into a very positive “sperm ejection.” In this ejection,

B&B saw a cryptic but powerful means for female influence on the outcome of sperm competition. They hypothesized that the female orgasm, both associated and not associated with copulation, was a central player in this influence.

B&B's studies of copulatory ejaculates (Baker and Bellis 1993a) were now sufficiently advanced to allow prediction of the number of sperm inseminated on any occasion. So, after counting the number of sperm in a flowback, B&B could estimate how many sperm had been retained by the female on that occasion. The female's orgasm history in the days, hours, and minutes preceding, during, and immediately after the copulation was provided, thus allowing the study of any link between retention and orgasm.

Both the occurrence/nonoccurrence and the timing (relative to copulation and moment of male ejaculation) of female orgasm influenced sperm retention. Orgasms at any time between 1 min before the male ejaculated up to 45 min after led to a higher level of sperm retention. Lack of climax or alternatively a climax during foreplay led to a lower level. So, too, for up to 8 days before the intercourse did "inter-copulatory" female orgasms (either spontaneous/nocturnal or masturbatory).

B&B concluded that the female orgasm generates a blow-suck mechanism that draws the contents of the upper vagina just a little way into the cervix, there to interface with the cervical mucus. These contents include sperm and seminal fluid if present, acidic vaginal fluids if not. Hence, inter-copulatory orgasms lower the pH of the cervical mucus and either slow down or kill any sperm that later attempt to penetrate. Inter-copulatory orgasms may also serve an antibiotic function.

With regard to sperm competition, B&B's main conclusion was that copulatory and inter-copulatory orgasms endow females with considerable flexibility in the manipulation of inseminates. In a single male "faithful" situation, a female's orgasm pattern is such that it reduces the number of sperm retained. During periods of infidelity, however, females change their orgasm pattern. These changes favor the sperm from the "lover" rather than the long-term partner and are cryptic to both male partners.

Final Joint Publication (1995)

After 1993, B&B never again published jointly in a peer-reviewed journal. Baker (2015) opines that because ethical committee dictates and health and safety restrictions (driven by the specter of AIDS) were by then beginning to bite, he and Mark Bellis may not have been allowed to continue in the cavalier way that suited them anyway. He adds, though, that in the end, this looming threat made no difference. Both researchers had already decided it was time to move on to new and different challenges. Before finally disbanding, however, they produced a book, *Human Sperm Competition*, published in 1995.

Primarily, B&B's book detailed their view that all aspects of human sexuality had been shaped in part or in whole by sperm competition. Further data were presented for all subject areas covered previously in their papers. In addition, however, they took the opportunity to address a few aspects of human sexuality for the first time. One of these, rape, was analyzed from the literature. Another, male and female homosexuality, they hypothesized, was adaptive. Data were presented from their *Company* survey which B&B claimed showed that bisexual women produced fewer children in their lifetime than heterosexuals but at an earlier age, thereby gaining a shorter generation interval.

Two further new hypotheses concerned male genitalia. One addressed the shape of the penis, in particular the fact that the erect human organ is straight and piston shaped with a smooth terminal protuberance (= glans). To B&B, this shape, the fit of the penis in the vagina, and the pumping/thrusting action during copulation all suggested a role in the removal of semen potentially inseminated previously by a different male. As the penis pulls back, sperm, seminal fluid, and cervical mucus are sucked down the vagina. On the next forward thrust, the glans pushes through this material and then on the next backward pull, the back edge of the glans scrapes the material further down the vagina. They summarized the process (Baker and Bellis 1995; p. 171) as "push-pull-suck-push-suck-push-pull-scrape."

The other new hypothesis addressed the testes, particularly size and variation. Testes size is

heritable. It is also extremely variable: in B&B's UK sample, the volume of the left testis ranged from 7–31 ml, a variability that they hypothesized reflected an evolved balanced polymorphism. On their hypothesis, men with larger testes are, in effect, sperm competition specialists, whereas men with smaller testes are mate-guarding specialists. Between the two extremes, individuals pursue a mixed strategy. In support of their hypothesis, they showed that men with larger testes (1) spend less time with their long-term female partner, (2) copulate more frequently, (3) ejaculate more frequently, and (4) are more likely to become involved in sperm competition.

The culmination of B&B's book was a detailed formulation of the Kamikaze Sperm Hypothesis along with a presentation of the first supporting evidence. Three categories of sperm were recognized: "egg-getters," to move through the female tract and fertilize any egg the female produces; "seek-and-destroy," to find, recognize, and destroy any sperm present from rival males; and "blockers," to settle and maybe agglutinate in numbers in any constricted passageway. The most likely of these constrictions, B&B suggested, were channels through the cervical mucus and the openings from the uterus into the oviduct. Speed, straightness of track, and other characteristics of the different sperm morphs were described, likely membership in one of the three categories assessed, and a range of supporting experimental evidence presented.

It was already known that fewer than 1% of sperm in mammalian, including human, ejaculates showed any "interest" in fertilizing an egg (Cohen and Massey 1984). B&B suggested, therefore, that egg-getters were a tiny (<1%) subset of the commonest morph (oval headed with single straight tail), a subset that appeared at a particular physiological age or stage. The heads of this most common morph vary in size along a continuum but, in B&B's studies, the mean size gradually increased as if growing with time after ejaculation. For descriptive convenience, B&B divided oval-headed sperm into three visual stages: micro, modal, and macro.

B&B's hypothesis, for which they offered supporting data, was that these micros, modals,

and macros represent different phases in development and behavior: while in micro form, the oval-headed sperm are in waiting; while in modal form, they behave as seek-and-destroy sperm; and while in macro form, some at least go in search of an egg. At any one time, therefore, there are around 1% of oval-headed egg-getters in the ejaculate, whereas the bulk of oval-headed sperm fulfil a seek-and-destroy role, this being the function that requires the greatest numbers.

Evidence for seek-and-destroy behavior was obtained through "mixing" experiments. On the assumption that such behavior would not be triggered until sperm had left the seminal fluid and were at least in the cervical mucus or even higher in the female tract, sperm were separated from the semen of two different men and mixed together in an appropriate medium. As a control, two subsamples of sperm from each man were also mixed self-with-self. The data collected included how many sperm die, how many form dyads (pairs of sperm joined at the head), and how many are swimming around without an acrosome (the "bomb on the head" that B&B suggested was the weapon sperm used to kill each other). More seek-and-destroy traces were predicted to be seen in "self-other" than "self-self" mixes. Over a long series of such experiments, B&B reported that the first signs of seek-and-destroy activity appear after 6 h, peak after 12 h, and are still evident, despite the sperm becoming generally less active, after 24 h.

With regard to blocker sperm, although B&B considered several of the less common morphs to be candidates, the one that attracted their attention most was the coiled-tail sperm. Once again, this was an "age" morph, essentially a slow old sperm (with normal tail) that when it settles in a channel of cervical mucus, it then coils its tail and, even if it dies, becomes obstructive enough to bar passage to any later sperm. B&B showed that self-self mixes of sperm formed frequent and sometimes large agglutinations of sperm. They also showed from their study of flowbacks that the more soon-to-be coiled-tail sperm that were inseminated at one copulation, the fewer sperm in total were retained by the female at her next copulation.

After publication of their book, B&B disbanded. Robin Baker left academia to become a full-time writer and to migrate with his family to southern Spain. Mark Bellis became a professor and director of the Centre for Public Health at John Moores University, Liverpool, UK, and was eventually awarded an OBE (Order of the British Empire) for “services to healthcare.”

Post-collaborative Publications

Although B&B never coauthored anything new after 1995, three further publications stemmed from the collaborative decade.

The book *Sperm Wars* (Baker 1996) was Robin Baker’s attempt to bring his and Mark Bellis’s work to a wider audience. As a collection of 37 short stories, the book shows people engaged in all aspects of sexual behavior. Each story is followed by an explanation of the role of sperm competition in the evolution of the behavior portrayed. Although primarily a popularization of the coauthored *Human Sperm Competition*, Baker did expand certain aspects. He also renamed seek-and-destroy sperm as “killer” sperm. The book has so far been translated into 25 different languages.

In 1997, Baker published a paper entitled *Copulation, masturbation, and infidelity: State-of-the-Art* based on his keynote lecture to the International Society for Human Ethology in Vienna in 1996. Baker used the opportunity to address criticisms B&B had received since the collaborative era and also presented three new analyses based on expanded B&B data. One showed that female strategy over contraceptive use, orgasm pattern, and infidelity changed over the transition from younger courtship to older reproductive phases of female lives. Another presented sperm counts from bisexual males alongside a data-based discussion of bisexuality as a reproductive strategy. A third, using the first ever ejaculates collected during acts of infidelity, showed that substantially fewer sperm were inseminated than sperm competition theory predicted. A new interpretation was offered.

Nearly 20 years after ending their original collaboration, B&B again worked together briefly to produce a digital version of their book *Human Sperm Competition* (Baker and Bellis 2014). In the preface to the new edition, they corrected a misunderstanding (see section “[Legacy: Growth of a Field, Support, and Opposition](#)”) that had arisen over egg-getter sperm.

Legacy: Growth of a Field, Support, and Opposition

The experimental methods developed by B&B were rooted in an era before health, safety, and ethical concerns were paramount. However, even by the time they disbanded, no other author had published an experimental paper on human sperm competition.

The delay meant that when other workers did at last begin to appraise B&B’s results and hypotheses, they had to confine themselves to less direct protocols. Early workers in the United States found ingenious ways to use and assess B&B’s work without actually collecting sperm, and later this approach was hugely and successfully expanded in many different ways by Todd Shackelford and the team he assembled at Oakland University, Michigan (Shackelford et al. 2016). Not until a decade after B&B’s departure were the first studies of whole ejaculates performed, and even these were restricted to collection during masturbation (ejaculates which B&B had shown could differ markedly from copulatory ejaculates: Baker (1997); Baker and Bellis (1989, 1993a)). The first studies involving copulatory ejaculates and flowbacks were delayed until 2016, though no results have yet been published.

B&B had pioneered several study areas within the broader field of human sperm competition. Levels of human sperm competition, male adjustment of ejaculates, function of the female orgasm, penis shape, variation in testes size, female behavior through the menstrual cycle, and sperm polymorphism have all since grown into subjects in their own right. As would be expected, some of B&B’s early hypotheses and results have been supported, and others have been questioned

(compare Birkhead 2000; Dixon 2009; Gallup and Burch 2004; Grammer et al. 2004; Kura and Nakashima 2000; Leivers and Simmons 2014; Pound et al. 2006; Shackelford et al. 2016; Thornhill 2006). Moreover, a few have been vigorously opposed.

The evolutionary approach to the female orgasm spearheaded by B&B was strongly attacked by Elisabeth Lloyd in her book, *The Case of the Female Orgasm: Bias in the Science of Evolution* (Lloyd 2005). After making clear her anti-evolutionary views, she then set about refuting B&B's work. Her attack was almost entirely statistical and concluded with the pronouncement that B&B's work on the female orgasm was "worthless."

B&B's hypothesis that men with large testes are "sperm competition specialists" has also aroused strong feelings. In his book *Promiscuity*, Tim Birkhead (2000; p. 25) describes the occasion that Baker first presented the hypothesis publicly. According to Birkhead, the lecture caused "sniggering incredulity" and "downright indignation" among some members of the academic audience. In his opinion, the work presented was "difficult to defend" and "naïve" and caused him to lose faith in Baker as a scientist. A few years later, Baker (1997) addressed the more constructive criticisms from that meeting and claimed that the hypothesis was still robust. At present, despite a "no evidence" paper by Simmons et al. (2004), all of B&B's testes size predictions have supporting evidence. The most recent such support comes from Mascaro et al. (2013) who demonstrate that men with larger testes show reduced parenting effort.

Of all B&B's hypotheses, the most contentious has been that of kamikaze sperm. Indeed, B&B have been attacked for this suggestion at a level far more personal than is usual in the academic literature. Tim Birkhead's "sexual fantasy" and "phallus in wonderland" comments are two examples, and Roger Short (1998; p. 22) provides another. He dismissed B&B's evidence that egg-getter sperm were an age category (macros) of oval-headed sperm by saying that they were no more likely to be egg-getters than they were "to contain little men." Such put-downs appear to

have been accepted by the field without question. Birkhead's assertion (Birkhead 1996; p. 29) that the kamikaze sperm hypothesis had been "repeatedly squashed" has led subsequent authors to accept, without any direct appraisal, that the hypothesis has been discredited.

The grounds for such categoric dismissals of the kamikaze sperm hypothesis are obscure. According to Baker and Bellis (2014), Short's "little men" comment was misplaced, a mistake based on his misinterpretation of their use of the descriptor "macro." No direct test of their egg-getter hypothesis has been attempted. Similarly, blocker sperm in humans have not yet been investigated. Although Moore et al. (1999) briefly mentioned that they may have found hints of such sperm, they chose to dismiss the possibility on the grounds that they were not searching for such evidence. Moore et al.'s paper also reports the only mixing experiments performed to date. Ostensibly the intention was to test for the presence of killer sperm, but the methodology rather suggests otherwise. B&B had shown that the first signs of killer activity appeared after sperm from two men had been mixed for 6 h and peaked after 12 h. Moore et al. stopped their experiments after only 3 h and, consistent with B&B's results, found no sign of killer activity up to this time. Why these researchers did not continue longer remains unexplained, and to date, no study has checked B&B's claims over what happens after 6–12 h. It is difficult, then, to see on what evidence B&B's kamikaze sperm hypothesis has been discredited even once, let alone repeatedly.

Exactly why B&B's work and ideas proved so divisive and generated such antagonism has never been made clear. Unless, that is, Tim Birkhead (2000; p. 29) intended the following as an explanation: "Baker's and Bellis's claims regarding human sperm competition were momentous and caught the public imagination almost to the same extent as Stephen Hawking's *A Brief History of Time*." Birkhead then asks "Why?" given that results from studies of sperm competition in other animals are "equally exciting, equally bizarre and far better substantiated, (yet) hardly ever make the press or television."

Conclusion

When Baker and Bellis first began their collaboration in 1985, the field of human sperm competition was no more than a daringly speculative paper by Robert Smith and a 20-year-old “impossible” fantasy for Robin Baker. Mark Bellis, though, could see how that fantasy could be developed into a scientific enterprise, and by the time B&B finished, they had created a whole field of study with many questions asked, a number provisionally answered, and a range of new experimental methods devised. Since then, through a mixture of support, questioning, and often caustic criticism, others have built on B&B’s foundations to turn human sperm competition into a major arena for biological, psychological, medical, physiological, anatomical, and most of all evolutionary study.

Role of Experience in Tool Use

Definition

Cognitive mechanisms (e.g., previous experience, learning) that play a role in tool-use contexts.

Introduction

In one of Köhler's classical problem-solving experiments, chimpanzees were presented with an out-of-reach banana suspended from the ceiling (Köhler 1925). Importantly, the only available “tools” in the room to solve the problem were some boxes. Chimpanzees' first reaction was to try to directly reach the banana. After a few initial unsuccessful attempts, several chimpanzees *suddenly* started to stack the boxes and eventually obtained the reward. When explaining their performance, Köhler stressed the *insightful* nature of chimpanzees' responses and argued that his chimpanzees solved the problem by an *immediate* reasoning process that reorganized their previous individual experiences (e.g., moving boxes, box in relation to reward) into a mental representation that allowed them to find the solution (Köhler 1925). However, Köhler's explanations were criticized since little was known about chimpanzees' previous learning history with boxes.

In this regard, Epstein et al. (1984) study with pigeons helped to shed light on the role that learning plays in problem-solving situations. In their experiment, Epstein and colleagues used operant conditioning to train pigeons to perform two different behaviors: (1) to push a box toward a target location on the floor and (2) to stand on a box and peck at an out-of-reach target (i.e., a toy banana) that was hanging over the box. Next, pigeons were presented with a new situation, in which the box was placed some distance away from the target toy. After a brief “confusion” period (approximately 2 min long), the three pigeons started to push the box toward the toy banana to finally climb up and peck the target. Importantly, those pigeons who were trained to perform only one of the two actions – either to push the box or to stand on the box and peck the target – failed to find the solution to the problem. What is significant about Epstein et al.' study is that pigeons' behavior seemed superficially as insightful as chimpanzees' behavior in Köhler's experiments. In fact, since pigeons were trained to perform the two separate actions and never to execute the combined sequence of actions, Epstein

et al. (1984) suggested that performing the two actions was an instance of insightful behavior. On the other hand, it is also possible that the actual mechanism underlying pigeons' performance is a synthesis of the previously trained behaviors (Epstein et al. 1984). In fact from an associative-learning approach, pigeons' behavior can be explained as follows: when the first response – orientation toward the target – is extinguished, the most coherent response to appear next is the previously trained “pushing the box” behavior. Once the distance between the box and the target has been reduced, the second previously trained behavior – peck the target – is performed.

Previous Experience vs. Training

The question is how chimpanzees and pigeons are solving the problem. Are they using the same cognitive mechanism? While it is true that little was known about chimpanzees' previous experience with the boxes, an obvious difference between the two studies is that whereas pigeons were shaped to reach the successful response, chimpanzees were not. As such, Call (2013) argued that while chimpanzees were able to *spontaneously* chain the two actions in order to solve the problem, pigeons' behavior was missing the *spontaneity* component. In this regard, those pigeons who were trained only to perform one of the two actions are informative because they failed to *spontaneously* solve the problem. However, the lack of training does not equate to the lack of experience (Call 2013). In fact, Birch (1945) found that previous experience with the distinct elements of the problems was required in order for chimpanzees to solve the Köhler's (1925) box problem. Importantly, this experience was acquired spontaneously – young chimpanzees pile boxes on top of each other while playing – rather than from an operant training program. Thus, “acquiring and using this information is quite different from training the pigeon to move the box under the target” (Call 2013 pp. 9). Along the same lines, Emery (2013) claims that insight does not underlie pigeons' performance. Based on Thorpe's (1964) definition of

insight – “the sudden production of a new adaptive response not arrive at by trial behavior or as the solution of a problem by the sudden adaptive reorganization of experience” (pp. 110) – Emery (2013) argues that pigeons' responses were trained (and therefore, not sudden or spontaneous), were not new, and were not restructured from *similar* previous behavior – but from the *same* previous behavior.

Regardless of how one interprets Köhler's (1925) and Epstein et al.' (1984) findings, everyone would agree that both studies highlight the importance of understanding how animals solve problems – particularly, if we are to understand the evolution of tool use. In the recent years, birds (e.g., New Caledonian crows, ravens, keas) and nonhuman primates (e.g., capuchin monkeys, chimpanzees, orangutans) have been shown not only to avoid traps, pull strings, use tools to release a platform, or use tools in sequence to obtain food but also to manufacture tools or to save and transport them for future use (e.g., Povinelli 2000; Shettleworth 2010a). However, despite the increasing number of studies, the question that still remains under heated debate is which cognitive mechanism underlies animals' performance in these tool-use tasks. While some researchers have argued that undoubtedly “insight” or “reasoning” can explain animals' behavior (e.g., Emery 2013), others have argued that simpler mechanisms – learning and associations – can account for their performance (e.g., Shettleworth 2010b).

Cognitive Mechanisms Involved in Tool Use

Why does the role of experience and learning *still* remain such a controversial issue in the context of problem-solving and tool use? As mentioned above, insightful solutions have been described as those solutions that appear *suddenly*, *after initial unsuccessful attempts*, and also involve certain *reorganization* of previous behaviors (e.g., Köhler 1925; Thorpe 1964). Importantly, in the human literature, insightful solutions have also been associated with a phenomenological and

subjective experience of a sudden realization of the solution to the problem – so-called “aha” moments (e.g., Bowden et al. 2005). Assessing subjective experiences – such as “aha” moment, mental time travel, or causal understanding – is extremely difficult when the subjects undergoing such an experience lack verbal abilities to express and share them (e.g., Shettleworth 2010b, 2012). On this point, Call (2013; see also Shettleworth 2012) argues that comparative research has tended to identify psychological process with the phenomenological experience associated with them. As such, the debate has been polarized into the two conflicting views – those arguing that (associative) learning is behind problem-solving and those arguing that (causal) understanding is behind problem-solving (e.g., Shettleworth 2012). While this debate has contributed enormously to the increase in the number of empirical studies on problem-solving and tool use, research has reached a point in which new theoretical and empirical approaches might be needed if we are to move the field forward.

In this regard, Call (2013) proposes three mechanisms to identify a “creative” problem solver: (1) acquisition of information, for example, through a trial-and-error process (e.g., reinforcement program) or exploration (e.g., during play), (2) organization of the information (i.e., recombining and restructuring previously acquired information), and (3) object manipulation (i.e., predisposition to explore and manipulate objects). By stepping out of the “associative learning vs. reasoning” debate, Call (2013) suggests a framework based on animals’ abilities to acquire, store, and use information in problem-solving situations. His proposal allows assessing animals’ performance in terms of “how much information (or what type) they need to solve a task and how separate different pieces of information have to be to still be able to produce a viable solution” (pp. 16). Thus, if problem solving is seen as a creative process in which different psychological processes are involved (Call 2013), methodologies will focus, for example, on how manipulating previous experience with a particular problem will affect animals’ abilities to generalize to new problem-solving contexts –

as opposed to investigate how animals solve entirely new problems.

Conclusions

While approaches like Call’s (2013) approach could shed light on which cognitive mechanisms underlie animals’ problem-solving skills, the question of insight might still remain open. This is particularly true since neuroimaging research with humans has shown that insight is a distinct cognitive process that is associated with specific brain areas (e.g., anterior superior temporal gyrus) (Bowden et al. 2005). Thus, new experimental paradigms will still be needed if we are to fully understand the role of experience in problem solving, in general, and tool use, in particular. Although challenging, the future of the study of problem solving looks bright. There is no doubt that there is still plenty of room for more research on the cognitive processes involved in tool-use contexts and the role that experience might play in them.

Romantic Attachment

Definition

Romantic attachment is a deep emotional, and often sexual, bond with another person. This idea of romantic love is believed to be the integration of the attachment system along with the caregiving system and the mating system (Hazan and Shaver 1987). Romantic attachment is comprised of two independent dimensions: avoidance of intimacy, or generalized beliefs that others are not

dependable and trustworthy, and anxiety about abandonment, or generalized beliefs about one's self, believing that one is valuable and worthy of affection. A romantic attachment characterized by low feelings of avoidance and anxiety is considered to be secure.

Introduction

When John Bowlby (1969/1982, 1988) originally proposed attachment theory, he conceived of attachment as extending over the entire lifespan and reasoned that our desire for attachment figures extends from “cradle to grave” (p. 62). In short, Bowlby argued that because of our vulnerability upon birth, humans have an attachment behavioral system or an evolved set of behaviors and reactions that ensure survival by keeping children close to their caregivers (Bowlby 1969/1982). Early work primarily focused on attachment in children and the bidirectional effects with caregiver interactions. In some of the earliest empirical work, Mary Ainsworth and her colleagues proposed three categories of attachment: secure, avoidant, or anxious/ambivalent (Ainsworth et al. 1978) – based on observed interactions between infants and caregivers in what has come to be known as the “Strange Situation” interaction. She and her colleagues found that when children were temporarily left with a stranger (i.e., researcher) in an unfamiliar room, they tended to respond in one of three distinct ways: (1) In the face of threat, some children feel secure, (2) others adopt an anxious/ambivalent hyperactivated strategy and demonstrate a strong desire to connect with and be reassured by their caregiver, and (3) others adopt an avoidant deactivated strategy, demonstrating a diminished desire to connect with or be reassured by their caregiver.

Cindy Hazan and Phillip Shaver (1987) were the first researchers to propose that the attachment system witnessed in the infant-caregiver relationship might be a reasonable explanation for adult romantic love. They proposed that using an attachment framework as a means to explain romantic love posed several advantages over then-existing models:

- (a) Given that love relationships may differ from couple to couple, a model of romantic love must be able to accommodate these and attachment allows for such differences.
- (b) Attachment theory explains how both healthy and unhealthy forms of love can develop as reasonable responses or adaptations to particular social circumstances.
- (c) Attachment theory explains the importance of separation and loss in infant-caregiver relationships and thus can explain why loneliness and love are related.
- (d) Attachment theory allows love to fit squarely within an evolutionary context.

In a series of two studies examining both community (Study 1) and student (Study 2) samples, Hazan and Shaver found evidence that the proportion of people endorsing each attachment style originally proposed by Ainsworth (secure, avoidant, and anxious/ambivalent) when considering their romantic relationships would match those found in infant-caregiver relationships (Hypothesis 1), the emotional experiences in one's romantic relationships (e.g., happiness, jealousy) differed based on one's attachment style (Hypothesis 2), people's working models for relationships correlated in predictable ways with their attachment styles (Hypothesis 3), and people's recollections of their parental relationships mirrored those of their current romantic attachment styles (Hypothesis 4). Study 2 also tested and found evidence that attachment styles were meaningful predictors of both state and trait loneliness (Hypothesis 5). Further, they concluded that their results provide evidence that romantic attachment and love, rather than being historical-cultural inventions, are biological and social processes with evolutionary roots.

Conceptualizing romantic love as an attachment relationship has become one of the major theoretical approaches in the study of romantic relationships (Fraley and Shaver 2000). The original Hazan and Shaver (1987) paper has been cited in PsycINFO 2940 times. In their review, Farley and Shaver (2000) propose that the idea of romantic love as an attachment relationship has become so popular because it provides a unifying

framework for understanding multiple aspects of relationship, including formation, maintenance, and dissolution, and does so by integrating findings from multiple fields such as psychology (including physiological, developmental, social, clinical), cognitive science, ethology, and even, psychodynamic thought.

Currently, romantic attachment theory proposes that based on experiences with a primary caregiver, people develop *internal working models of attachment* that they use in their romantic relationships (Bretherton and Munholland 1999). Adults whose caregivers were consistent and reliable in their support provision go on to form secure romantic attachments, characterized by low avoidance and low anxiety. They have positive views of themselves, believing that they are worthy of love, and have positive views of others, believing that close others can be relied up for effective support and help should they need it. This allows for a great deal of flexibility and openness to dealing with relationship stresses and threats. Adults whose caregivers were more inconsistent develop insecure romantic attachments. Those who have negative views of themselves as worthy of affection but see others as a possible source of care and comfort adopt *hyper-activating strategies*, clinging to and trying to control their romantic partners in an attempt to ensure support when needed. This is consistent with a more anxious romantic attachment. By contrast, those who have positive views of themselves, seeing themselves and valuable and worthy of affection, but have negative view of others as being able and willing to provide comfort and support, adopt *deactivating strategies*. These strategies involve denying one's attachment needs and prioritizing independence in an attempt to ensure that one is self-reliant and will not need support. This is consistent with a more avoidant romantic attachment.

How Romantic Attachment Differs and Develops from Infant-Caregiver Attachment

Although derived from the infant-caregiver attachment system developed in early life, there are important distinctions between romantic attachment and this earlier attachment system.

Primarily, the difference lies in the symmetrical, or mutual, nature of adult romantic relationships, meaning that both romantic partners seek each other out and provide support to one another. This is different than the asymmetrical nature of the earlier attachment with a caregiver, with support provision being provided solely by the caregiver. In addition, romantic relationships frequently serve a sexual, or mating, function which is absent in the infant-caregiver relationship.

According to Bowlby's original conceptualization (1988), attachment relationships are characterized by four distinct features. First, individuals want to be physically close to their attachment figure and are motivated to maintain this closeness (*proximity maintenance*). Second, when individuals are upset or face uncertainty or stress, they turn to their attachment figure for consolation and reassurance (*safe haven*). Third, individuals protest separation from their attachment figure and show distress during prolonged and/or unanticipated absences (*separation distress*). Finally, individuals use their attachment figure as a foundation, or base, from which they explore their environments and engage in new activities (*secure base*). (Conceptualizations of proximity maintenance frequently include the separation distress component, and therefore, some works discuss three components of attachment.) Attachment theory proposes that in adulthood, one redirects the attachment initially experienced with one's caregiver to a romantic partner and in turn, it is the romantic partner who becomes the primary attachment figure. Although peers or other close others (e.g., siblings) may fulfill some of these attachment functions, it is unlikely that they will possess all of the necessary characteristics, making romantic pair bonds actual attachment figures (Hazan and Diamond 2000).

Hazan and Zeifman (1994) discovered that these components are transferred to one's romantic partner in a specified order – one's proximity maintenance, followed by safe haven, and ending with secure base. Further, they found that 80% of their sample relied on their romantic partner for all three of these attachment functions by two years into their romantic relationship. Subsequent work by Farley and Davis (1997) and Fagundes and

Schindler (2012) has confirmed this two-year time span for romantic partners to be seen as full attachment figures. Fagundes and Schindler (2012) also found that at time of formal commitment to a relationship, people perceived their romantic partners as the primary attachment target for proximity seeking and secondary attachment targets for safe haven, suggesting that attachment formation had its origination during more casual dating phases of a relationship. Seeing one's partner as a secure base did not increase during casual dating and was the last attachment function to be transferred to the romantic partner. Of note, these authors also point out that although individual differences in the speed of attachment transfer did emerge from people of different attachment orientations (e.g., anxious romantic attachment was associated with seeking proximity from a romantic partner earlier in the relationship), attachment transference to romantic partners does follow a normative pattern of proximity seeking, safe haven, and secure base.

If romantic attachment stems from infant-caregiver attachment, then there should be some correlation between the two attachment experiences. The original work done by Hazan and Shaver (1987) made connections between the current romantic attachments people reported and their concurrent recollections of parent attachments. Subsequent research has adopted longitudinal methods to better assess this potential connection. Roisman et al. (2005) found a 61% correspondence between participant's current romantic attachment (assessed at age 20–21 with a semi-structured interview) and infant-caregiver attachment assessed at 12 months and 18 months of age with the Strange Situation. Pascuzzo et al. (2013) found a link between parental insecure attachment (assessed in adolescence with a self-report measure) and anxious romantic attachment (assessed 8 years later with a self-report measure) but did not find a link with avoidant romantic attachment.

Romantic Attachment as Evolved Mechanism

In the original conceptualization of romantic love as romantic attachment, Hazan and Shaver (1987) noted a benefit of their conceptualization as being

grounded in evolutionary theory. The similarities between romantic attachment in adulthood and infant-caregiver attachment (proximity seeking, safe haven, secure base) are regarded as “behavioral homologues,” meaning that they foster the same goals and are affected by the same types of conditions (Fraley and Shaver 2000). In considering the integration of the attachment, caregiving, and mating systems, Shaver et al. (1988) suggested that pair-bonding, or romantic attachment, may have evolved to enhance offspring survival. This idea was further discussed by Fraley and Shaver (2000), whose review of the literature suggested that romantic attachment/pair-bonding is beneficial as it prevents issues related to paternal certainty for men by keeping partners close together and it provides additional protection for vulnerable offspring, increasing the likelihood that they reach maturity. However, their review also pointed out that this account may be insufficient as pair-bonding is relatively rare in other species, which seems unlikely if it is uniformly advantageous. Further, pair-bonding does not automatically guarantee increased investment in one’s offspring.

Several studies have examined the evolved nature of pair-bonding specifically. Research by Fraley et al. (2005) examined archival data of a variety of animals (Study 1) and primates exclusively (Study 2) and concluded that pair-bonding and parental care appear to have co-evolved and are homologous/functional (rather than simply analogous). Further, parental care appears to emerge first, followed by pair bonding. By way of example, they mention a study’s finding that oxytocin is released both when people mate and when they take care of their offspring. This suggests that the same biological outcomes are occurring in both behaviors, thereby facilitating romantic attachment. The issue of romantic attachment being an adaptation to address the unique human challenge of concealed ovulation has also been discussed. Eastwick and Finkel (2011) note in their literature review that infant-caregiver bond evolved approximately 35 million years ago, but the romantic attachment bond probably evolved much more recently, at roughly the time of the appearance of the genus *Homo*,

approximately 1.5–2 million years ago. Their research further found that naturally cycling women (i.e., those not taking hormonal contraceptives) who reported a strong romantic attachment bond to their current partner and were at increased likelihood of conception reported stronger sexual motives than women who did not report such romantic attachment. They concluded that “attachment processes appear to capitalize on the ovulatory motivation to desire sex with particular men and re-channel that motivation in a manner that potentially strengthens the attachment bond” (p. 180).

Measurement of Romantic Attachment

Alongside the theoretical development of adult attachment theory, there has also been considerable development in how attachment is measured. In the seminal article by Hazan and Shaver in 1987, the approach was to use the three attachment types/styles originally identified by Ainsworth’s work on infant-mother attachment (see Ainsworth et al. 1978) to categorize adults in terms of their attachment to romantic partners in general. In this original approach, Hazan and Shaver (1987) provided three type-descriptions in the realm of romantic relationships that were analogous to the three infant categories: secure, avoidant, and anxious/ambivalent. For instance, secure attachment was described as, “I find it relatively easy to get close to others and am comfortable depending on them and having them depend on me. I don’t often worry about being abandoned or about someone getting too close to me.”

Since this initial approach to measuring attachment, researchers have developed more sophisticated tools. One of the early major developments in measurement was introduced by Bartholomew and Horowitz (1991) with a scale called the Relationships Questionnaire (RQ). The RQ, and the associated theoretical model, were defined by two changes. First, the RQ introduced a conceptualization of adult attachment that argued for a fourth style that reflected a second kind of avoidance known as dismissing-avoidance. Second, the RQ shifted toward a continuous measurement of attachment that reflects the consensus that

individuals are not necessarily in one category or another, but rather fall somewhere along a continuum. At the center of this model were two dimensions: Anxious Attachment and Avoidant Attachment.

By measuring people along these two continuums, researchers are able to conceptualize the four attachment styles as essentially different levels of anxious and avoidant attachment (see Fig. 1). In this approach to measurement, secure attachment is denoted by being relatively low on both dimensions of anxious and avoidant attachment, indicating relatively few insecurities. Relatively high scores on both anxious and avoidant attachment dimensions denote fearful-avoidant attachment. A relatively high score on the anxious dimension and low score on the avoidant dimension reflect preoccupied attachment. Finally, dismissing-avoidant attachment reflects being relatively high on the avoidant attachment dimension and low on the anxious attachment dimension. This two-dimension approach to measuring attachment – anxious and avoidant – continues to be used by modern scales.

A few years later, Brennan et al. (1998) put forth a new 36-item scale called the Experiences in Close Relationships (ECR) scale. To do so, they conducted a large-sample factor analysis that included all self-report measures of attachment at the time. This factor analysis revealed 12 specific-

construct factors that formed higher-order factors that reflected anxiety and avoidance. This scale was later revised into the ECR-Revised (ECR-R; Fraley et al. 2000), which is composed of 36 items, including two 18-item subscales that measure anxious attachment and avoidant attachment. To date, the ECR-R is the recommend scale for self-reports of general adult attachment.

As theoretical perspectives on attachment continued to develop, researchers have attempted to update and modernize the ECR-R. One trend among researchers is to develop shorter scales. Because participants have limited attention spans and researchers have limited resources, there is a constant push to develop faster and less burdensome measures. This has led to several shorter versions of the ECR, which include a 12-item version referred to so the ECR-Short Form (Wei et al. 2007) and a 9-item version known as the ECR-Relationship Structures scale (ECR-RS; Fraley et al. 2011). In general, both of these scales can be used as abbreviated versions of the ECR-R and retain the same factor structure, including both anxious and avoidant dimensions.

Another important recent development teasing apart differences between global working models of relationships and working models of specific attachment figures. Specifically, these scales allow researchers to identify a specific target for the questions, such as a current romantic partner, best friend, or a family member. This approach is exemplified by ECR-Relationship Structures scale (ECR-RS; Fraley et al. 2011). As noted above, the first measure developed by Hazan and Shaver (1987) focused on how people generally feel about relying on close others. This was also the approach used in developing the RQ, ECR, and the ECR-R. In general, these approaches have the strength of applying to people regardless of who their current attachment figures are. However, this may also serve as a weakness in some research contexts. Using the traditional scales is potentially problematic, as most self-report measures are designed to assess romantic attachment and thus contain items that do not translate to nonromantic partners (e.g., “When my partner is out of sight, I worry that he or she might become interested in someone else”). For instance,

Romantic Attachment, Fig. 1 Two-dimension model of attachment

La Guardia et al. (2000) were interested in within-person variability in attachments across relations (romantic partners, friends, and family members) as a function of various relationship qualities. This type of research question is dependent upon the ability to conceptualize and measure attachment as a relationship-specific variable.

Finally, there is considerable interest among modern adult attachment researchers in assessing attachment as a state, rather than a trait variable. That is, rather than conceptualizing attachment as “locked in” and stable over time or across relationships, that it is sensitive to situational and contextual factors. From this perspective, although attachment may generally exhibit stability over time, it is also a function of continued experiences. For instance, recent work has shown that there is considerable variability in attachment over time within relationships, which has subsequent implications for relationship functioning (Girme et al. 2018). Further, recent theoretical advances in attachment theory propose short-term and long-term mechanisms for how individuals’ attachment changes over time in adulthood (Arriaga et al. 2018). Although a full description of these works is beyond the scope of this entry, as our understanding of how attachment fluctuates across time, situations, and relationships continues to advance, there will be a need for increasingly sophisticated tools for measurement.

Linking Romantic Attachment and Relationship Outcomes

Variations in romantic attachment have long been thought to predict relationship outcomes. Specifically, secure romantic attachments are thought to be more beneficial for relationships compared to insecure romantic attachments. In their original study, Hazan and Shaver (1987) found that secure romantic attachments were generally associated with more positive and less negative relationship outcomes. (The specific pattern of results depended on whether the sample was drawn from a community or undergraduate population.)

Two meta-analyses have since been conducted to examine the subsequent research that has since been produced. Li and Chan (2012) examined the two dimensions of attachment (avoidance of

intimacy and anxiety over abandonment) and their prediction of several indices of relationship quality (including positive and negative cognitive, emotional, and behavioral outcomes) in 73 studies, including 118 separate samples and 21,602 participants. Most measures of relationship quality (with the notable exception of negative cognitive indicators) were weakly to moderately associated with avoidant and anxious romantic attachment; these insecure attachments were linked to increased negative relationship quality indices and decreased positive relationship quality indices. In addition, avoidant romantic attachments were more negatively associated with the positive relationship qualities when compared to anxious romantic attachments.

Hadden et al. (2014) examined the same two dimensions of attachment but focused exclusively on relationship satisfaction as the indicator of relationship quality and relationship commitment as the indicator of relationship strength/stability. Their meta-analysis included 57 independent effect sizes including a total of 14,340 participants. Both anxious romantic attachment and avoidant romantic attachment were negative predictors of relationship satisfaction, with the avoidant-satisfaction association being stronger than the anxious-satisfaction association. The same pattern of results was found for relationship commitment. The authors also examined whether the above relationships were moderated by relationship duration. The link between relationship satisfaction and both anxious romantic attachment and avoidant romantic attachment became more negative as relationships progressed. In other words, insecure romantic attachment’s correlation with relationship satisfaction was more negative for people whose relationships were of a longer duration when compared to people who were in shorter relationships. Due to an insufficient number of studies, the analyses examining insecure attachment and commitment were underpowered, but results suggested a similar pattern of results. Although not statistically significant, the correlation between avoidant romantic attachment and anxious romantic attachment and relationship commitment became more negative as relationship duration increased.

Individual Differences in Romantic Attachment

Researchers have been curious whether there are individual differences in people's experiences of romantic attachment.

Age Differences

An interesting line of research has considered whether romantic attachment changes over the lifespan. In their literature review, Chopik and Edelstein (2014) propose that in response to changing reproductive strategies and adoption of new roles and then later lack of such changes, anxious and avoidant romantic attachments are likely to be more or less stable as people age. In a sample of 90,904 adults aged 18–64 from 11 world regions, they found that anxious romantic attachments were highest among young adults and were lower in middle-aged and older adults, whereas avoidant romantic attachment showed the opposite pattern, with younger adults having the lowest levels and middle-aged and older adults having higher levels. However, the trajectory of age-related changes was flatter (i.e., smaller) for avoidance when compared to anxiety. The authors also note that the size of the changes across the lifespan are relatively small, supporting the contention that one's romantic attachment is relatively stable in adulthood.

Sex Differences

In the original work on romantic attachment, Hazan and Shaver (1987) did not propose theoretical reasons for or predict sex differences in people's romantic attachments. In his meta-analysis of sex differences in romantic attachment, Del Giudice (2011) discusses this "tacit consensus in the field that sex differences do not exist, or at least can be safely ignored" (p. 193) but also reviews work that proposes that romantic attachment may also reflect different mating strategies, which are reliably associated with sex differences (e.g., males report being more comfortable with short-term mating arrangements than females do). Further, he makes the argument that attachment mechanisms are but one behavioral manifestation of a larger factor, life history

strategies. In his analysis of 112 independent samples from 100 published and unpublished studies resulting in data from 65,047 participants, females reported higher anxious romantic attachments than males and males reported higher avoidant romantic attachments than females, but the overall effect sizes were very small ($-.04$ and $.02$ respectively). However, significant variability existed between sample types, with substantially larger sex differences emerging in community samples compared to student and web-based samples. Closer analysis of the distribution of scores using relative density plots found that sex differences were more substantial at the upper and lower levels of avoidant romantic attachment and at the extremes of anxious romantic attachment.

Both meta-analyses discussed earlier examined whether the links between romantic attachment and relationship outcomes were moderated by gender. Li and Chan (2012) found that gender was a weak moderator of the associations between romantic attachment and positive and negative relationship qualities. Hadden et al. (2014) found that gender did significantly moderate the negative relationship between satisfaction and avoidant romantic attachment (with the relationship between the variables being more negative for women) but did not moderate the satisfaction-anxious romantic attachment relationship. Gender did not significantly moderate the avoidant romantic attachment-commitment relationship and was only a marginally significant moderator of the anxious romantic attachment-commitment relationship.

In sum, it seems that Del Giudice (2011) may have been correct in concluding that "a strictly sex-neutral view of romantic attachment does not seem tenable any longer" (p. 204) and it seems prudent that future research should pay closer attention to the size and nature of sex differences.

Cultural Differences

Despite its grounding in evolutionary theory and the universality that can imply, there may be cultural differences in romantic attachment given that fact that there is little argument that cultural

differences in both parenting practices and romantic relationship dynamics exist (Schmitt 2010). It appears that the internal working models of attachment are similar across cultures, but they degree to which they are endorsed does differ. In his review of data from the International Sexuality Description Project (ISDP-2) which assessed people from 58 countries in 11 world regions, Schmitt found substantial differences in the proportion of people in each region who endorsed a secure romantic attachment. Although secure romantic attachment (low feelings of attachment anxiety and avoidance) is associated with better relationship outcomes, only one world region of the 11 assessed (Northern Europe) had over 50% of its population reporting this type of romantic attachment. Six of the 11 world regions reported less than 40% of its population endorsing a secure romantic attachment. In addition, substantial variations exist between world regions in the discrepancy between internal working models of the self and internal working models of the other. Further, cultural factors such as individualism/collectivism and ecological stress significantly predicted differential patterns of romantic attachment.

In the meta-analysis of sex differences discussed above (Del Giudice 2011), significant variability in sex differences was also seen when samples were separated into geographic region, with the largest differences emerging in Europe and the Middle East and the smallest differences seen in North America. Of note, there was cultural similarity in the direction of effects, such that males scored higher in avoidant romantic attachment and females scored higher in anxious romantic attachment (with the exception of East Asia where no significant sex differences in anxious attachment emerged). In their study of 11 world regions, Chopik and Edelstein (2014) did not find evidence of collectivism-individualism moderating the relationship between age and romantic attachment.

Sexual Orientation

Although research has suggested that there are more similarities between same-sex and

heterosexual couples than differences, the question of whether romantic attachment is related to sexual orientation was addressed by Ridge and Feeney (1998). The results of their study concluded that gay and lesbian participants reported similar patterns of romantic attachment when compared to a control sample of heterosexual participants. Consistent with studies focusing on heterosexual couples, Mohr et al. (2013) found that their partnered gay and lesbian participants who reported more avoidant and anxious romantic attachments also reported relationship experiences that were less positive (e.g., less satisfaction, less trust). The link between romantic attachment and relationship outcomes was in the same direction for both gay and lesbian participants although some relationships were stronger for gay men than lesbian women, suggesting some gender moderation.

Conclusion

The concept of romantic attachment has provided one of the most generative frameworks over the past 30 years for understanding adult romantic relationships and pair-bonding. Originally proposed by Bowlby as a way to understand processes underlying caregiving, researchers have expanded this work to develop a deeper understanding of adult romantic relationships. Some of the most important principles surround the development of enduring insecurities regarding working models of romantic partners, and how those insecurities affect our approaches to handling stressful situations, to seek and provide support, and ultimately our ability to maintain our romantic bonds. Ultimately, this field of work provides one of the most valuable theoretical frameworks for understanding social relationships across the life span.

Developmental correspondence between childhood and romantic attachment

Definition

In the normative course of development, individuals gradually transfer attachment functions

from the child-caregiver relationship to peer relationships, principally to romantic relationships. According to the prototype hypothesis, early attachment experiences influence the development and quality of subsequent close relationships. Drawing on this hypothesis, it has commonly been thought that individual variations in romantic attachment partly reflect individual variations in early caregiving experiences.

Introduction

Romantic attachment denotes an individual's stance regarding attachment-related aspects of romantic relationships, as manifest, for example, in the ways in which one uses the partner, and allows the partner to use oneself, as a safe haven for regulating distress, and as a base of security when exploring. Individual variations in romantic attachment have been found to exert significant influence over important aspects of relationship functioning, including relationship intimacy, communicative strategies, and emotion regulation (see ► [“Attachment in Adulthood”](#)).

In trying to explain these variations, researchers have commonly drawn on what has been termed “the prototype hypothesis” (Bowlby 1973). According to this hypothesis, early attachment experiences influence the development and quality of subsequent relationships over the life span. Thus, variations in romantic attachment have been thought to be rooted in individual differences in early caregiving (e.g., Hazan and Shaver 1987). This entry begins with a brief description of important similarities and differences between childhood and romantic attachment, followed by the theoretical rationale for assuming a correspondence between the quality of the early child-caregiver relationship and subsequent romantic attachment style. Finally, the entry reviews existing evidence for the prototype hypothesis with regard to romantic relationships.

Childhood and Romantic Attachment: Similarities and Differences

Attachment in childhood denotes the affectional bond that children form to their caregiver(s), seeking to maintain proximity to and protesting separations from their caregiver(s), using the caregiver(s) as a secure base to explore the environment from and a safe haven to return to for comfort and protection (see ► [“Offspring–Parent Attachment”](#)). In the course of development, these attachment functions are typically transferred to the relationships of adult life, principally to romantic relationships. This is thought to occur via a gradual process, starting in middle childhood and ending in late adolescence or early adulthood. A large body of evidence supports the notion of long-term romantic bonds as the normative instantiation of attachment in adulthood. For instance, child-caregiver and romantic relationships display unique similarities regarding the sequence of relationship formation, verbal and nonverbal communication, reactions to separation and loss, and the use of the caregiver/partner as a safe haven for emotion regulation. Moreover, the respective relationships have a similar and uniquely powerful impact on physical and psychological well-being, and are underpinned by a number of uniquely shared neural and endocrine features (for a more detailed account, see ► [“Attachment in Adulthood”](#)).

Importantly, although the individual functions of attachment bonds largely remain unaltered in the process from childhood to adulthood, a number of important changes are, however, also thought to occur. First, the increased cognitive and emotional maturity of adulthood leads to important differences between child and adult attachment dynamics, not least regarding the capacity to tolerate separations. Second, in romantic relationships, the attachment system is thought to become integrated with the sexual mating and caregiving systems. As a result, sexual attraction is usually the precipitating force that brings adult partners into close contact, rather than need for comfort and protection. Third, the asymmetrical nature of child attachment relationships becomes substituted for more symmetrical

relationships, with adult partners mutually seeking and providing security (Mikulincer and Shaver 2016).

Theoretical Background of the Prototype Hypothesis

The prototype hypothesis is based on Bowlby’s (1973) notion that early experiences with primary caregivers gradually become internalized, forming internal working models of self and others (IWMs; cognitive-affective representations; see ► [“Effects of Attachment Quality and Organization”](#)). The IWMs are thought to display a relatively high degree of continuity under stable environmental conditions, and to become generalized to other close relationships later in life, where they (mainly unconsciously) guide the individual’s expectations on and behavior towards others in attachment-relevant situations. Thus, it makes theoretical sense to hypothesize that early attachment experiences affect how the developing individual relates to subsequent romantic partners.

It should, however, be noted that the prototype hypothesis entails no full correspondence between childhood and romantic attachment. Bowlby carefully stated that the main function of IWMs is to foster adaptive behavior in the individual’s actual environment. Hence, changes in the environment, for example, in the form of new interpersonal experiences, might require the IWMs to be updated. Moreover, most scholars today regard IWMs to be organized hierarchically, with generalized models of self and others at the top, models for classes of relationships (e.g., caregivers, romantic partners) at an intermediate level, and models for specific relationships (e.g., mother, present partner) at the bottom (see ► [“Attachment in Adulthood”](#)). While the generalized models are thought to inform perceptions of self and others on the lower levels in a top-down manner, new relationship experiences with a specific partner could also, in a bottom-up manner, affect the models for the class of romantic partners, without altering the models for caregivers. However, since the generalized models

derived from relationships with caregivers are thought to found the basis for subsequent models on other levels, some degree of correspondence is still expected.

Empirical Evidence for the Prototype Hypothesis with Regard to Romantic Attachment

Romantic Attachment and Retrospective Measures of Childhood Attachment

Early investigations of the prototype hypothesis mainly relied on adults' self-reported memories of attachment-related experiences in childhood. A number of these studies supported the hypothesis. For instance, Hazan and Shaver (1987) found secure romantic attachment to be associated with memories of warmer and more caring relationships with parents. Avoidant individuals were more likely to remember their mothers as cold and rejecting, while anxious individuals tended to remember their fathers as unfair. The results are, however, weakened by notable methodological limitations, not least the obvious risk for reconstructive memory biases inherent in retrospective self-reports.

A number of studies have also examined the prototype hypothesis, by relating self-reported romantic attachment to concurrent classifications on the Adult Attachment Interview (AAI; see ► [“Attachment in Adulthood”](#)). The AAI is an in-depth interview measure, shown to possess psychometrical robustness with regard to parent-related working models in adults. If parent-related IWMs serve as prototypes for subsequent romantic relationship IWMs, the working models captured by the AAI should be associated with measures of romantic attachment (given that the measures employed in romantic attachment research are valid with regard to romantic IWMs). Studies based on this line of reasoning have, however, shown inconsistent results, typically demonstrating weak and at best moderate associations (e.g., Shaver et al. 2000).

There is, however, reason to believe that this inconsistency is partly a result of measurement issues. For instance, the self-reports

predominantly used when assessing romantic attachment likely capture limited, conscious parts of an individual's IWMs. In reality, IWMs are to a large extent unconscious, due, for example, to defensive exclusion of painful information from awareness (see ► [“Psychodynamic Foundations”](#)). This might cause trouble for researchers employing self-reports – especially when studying insecure forms of attachment, because insecurity is characterized by incoherent IWMs, as manifest, for instance, in conscious self-perceptions that are incompatible with the individual's actual (unconsciously motivated) organization of behavior in attachment-relevant situations. Supporting this line of thought, a tendency has been found in individuals classified as dismissing/avoidant on the AAI to report themselves as secure on self-report measures (DeHaas et al. 1994).

Romantic Attachment and Prospective Studies of Attachment Beginning in Early Childhood

Due to the children from some extensive studies of the 1970s to the 1990s now having reached adult age, it has become increasingly possible for researchers to examine the prototype hypothesis prospectively. In one such study, secure infant attachment was prospectively associated with secure romantic attachment representations in young adults, as measured by an in-depth interview measure. Secure infant attachment was also associated with higher observed relationship quality and more positive self-reported perceptions of the partner (Roisman et al. 2005).

Associations between early attachment and young adults' self-reported romantic attachment have also been reported. For instance, high quality maternal caregiving at 18 months has been associated with lower self-rated avoidance and anxiety in young adults' romantic relationships (Zayas et al. 2011). Partly in line with these findings, higher maternal nurturance, as measured by emotional openness, responsiveness, and control, has also been linked to lower levels of self-reported romantic avoidance – but not anxiety – in young adults (Chopik et al. 2014). Genetically based differences regarding the

susceptibility to environmental influence on subsequent romantic attachment have also been suggested. In a study following over 1000 participants, higher maternal sensitivity in childhood was linked to lower self-reported avoidance in adult relationships, but only among carriers of a certain variant of a serotonin receptor gene (Salo et al. 2011).

In the most ambitious longitudinal study to date, Fraley and colleagues (2013) investigated a large number of potential antecedents to self-reported global (i.e., across all relationships) and romantic adult attachment. This study found no substantial correlation between childhood attachment classifications and subsequent romantic attachment. However, lower maternal sensitivity, maternal depression, and father absence in childhood were predictive of higher global avoidance in late adolescence. Individuals reporting avoidance in romantic relationships were also more likely to have experienced decreases in maternal sensitivity over time. Few caregiving-related antecedents were found with regard to attachment anxiety, except that anxious individuals were more likely to have experienced increases in maternal depression during childhood. In examining potential genetic contributions to romantic attachment, this study largely failed to replicate the findings obtained by Salo and colleagues (2011). Interestingly though, the findings by Fraley and colleagues (2013) emphasized the importance of extra-familial relationships for romantic attachment, with social competence and the quality of close friendships over time being more robustly linked to subsequent global and romantic avoidance, than changes in family of origin variables.

In sum, the reported associations have not been strong and consistent enough to offer a reliable set of predictors for romantic attachment. Conclusions are also hampered by methodological limitations, not least the inconsistency with regard to the measurements used for assessing aspects of caregiving in childhood. Future research will be important to illuminate some of the present unclarity. It has, however, been

pointed out that, due to the enormous number of factors involved in shaping an individual's interpersonal development, weak associations should perhaps be expected (e.g., Fraley et al. 2013). In line with the mentioned association between romantic attachment and extrafamilial relationships, romantic attachment styles have been shown to be influenced by a number of factors beyond early caregiving experiences, including more recent and ongoing relationship experiences, and major life events such as the transition to parenthood (see Mikulincer and Shaver 2016). The explanatory power of any specific factor relative to the others will therefore likely be diminished. Thus, even if early experiences are important for maintaining a lifespan perspective on attachment and subsequent interpersonal functioning, they might not be essential for answering proximal questions about romantic attachment.

Conclusion

Partly supporting the prototype hypothesis, individual variations in romantic attachment are associated with attachment-related experiences in childhood. However, associations are neither strong nor consistent enough to offer a reliable set of predictors for romantic attachment. Findings also indicate that a number of factors beyond early caregiving are involved in shaping romantic attachment styles. This complexity underscores the importance of including a broad set of developmentally relevant factors, in future research attempting to shed further light on the etiology of romantic attachment.

Ronald Aylmer Fisher

Jeff Davis
California State University, Long Beach, CA,
USA

Sir Ronald A. Fisher was born on February 17, 1890, in East Finchley, England, and died on July 28, 1962, in Adelaide, Australia (Yates and Mather 1963). It was a life full of high accomplishments. Fisher built an enduring foundation for the advancement of multiple scientific fields. In evolutionary biology, Fisher is one of the three architects of the Modern Synthesis – theoretical work which elicited the genetic mechanisms and consequences of natural selection. Fisher (1999), Sewall Wright (1981), and J. B. S. Haldane (1993) each made unique insights on the genetic processes that lead to the evolution of phenotypes. Fisher (1999) introduced the concepts of life history, reproductive value, and runaway selection –

all of which have been central to theoretical advancements in fields such as evolutionary developmental biology, animal signaling, behavioral ecology, and evolutionary psychology. Fisher and Wright founded the field of population genetics. Their independent contributions to understanding genetic drift have been synthesized into the Wright-Fisher model of genetic drift (Crow 2002). Fisher is more famous for his work in statistics. Volumes of published scientific research have relied upon Fisher's methods of estimation and tests of statistical significance. Fisher's life and his enormously invaluable contributions to science have been thoroughly documented (Box 1978; Crow 1990; Edwards 2014; Moore 2007; Skipper 2007; Yates and Mather 1963). However, his sociological analyses have received scant attention. Yet, his ideas could serve well as a foundation for the development of evolutionary social sciences.

Fisher's "Sociological Views"

From one perspective, Fisher's interest in what he called "man's sociological development" was bound to occur (Fisher 1999, p. 184). Throughout most of his life, Great Britain was at the height of its power and global domination. In its rise to dominance, British forces effectively ended the Dutch, Portuguese, French, and Spanish empires. British archaeologists and historians continued to compile a vast wealth of knowledge about the rise and fall of ancient empires. British anthropologists were compiling an equal amount of data on the characteristics of indigenous peoples around the world. At home, sociologists were addressing questions about the rise and fall of European ruling classes and proffering teleological models of societal evolution. Perhaps most important of all was rapidly growing eugenics movement in England. Much like Darwin sought to elicit the mechanisms of natural selection, Fisher sought the mechanisms of social selection. The subject of social evolution was a major theme in his book, *The Genetical Theory of Natural Selection*. He devoted the second half of it to social evolution. He wrote:

While genetic knowledge is essential for the clarity it introduces to the subject, the causes of the evolutionary changes in progress can only be resolved by an appeal to sociological, and even historical facts. (Fisher 1999, p. 174)

In his view, the evolutionary success of a society depended upon the degree of the inversion in the relationship between social position and fertility. He proposed that the longevity of a social system ultimately depends upon the degree to which social position facilitates adaptive fertility behaviors (Fisher 1932). If social organization is the product of the optimizing tendencies of natural selection, positions higher up in the hierarchy should yield conditions most favorable to fertility. In this way the characteristics of higher-ranking members would be reproduced via biological and sociological mechanisms in offspring. Fertility rates would scale upward with position in a social hierarchy (Fisher 1932, 1999). Fisher (1999) pointed to the fact that in "savage" and "barbarous" societies (Fisher's references to "savage" and "barbarous" societies reflect European ideologies of racial supremacy and global dominance. Fisher seemed to make the following distinctions. A "savage" society lacks spatial and temporal stability and operates with minimal social control systems. A "barbarous" society has more formal social control systems that are strongly aligned with kinship. Social divisions are maintained by "blood feuds." Its language system is more complex, and its cultural knowledge is accumulated. "Civilized" societies operate formal systems of social control and cultural knowledge accumulation. Darwin and Fisher seemed to reject the moral sentiments normally attached to "savage," "barbarous," and "civilized." Darwin (1871/1998) argued that all civilized societies evolved from savage states of existence. Fisher (1999) argued that "civilized" societies were no less susceptible to natural forces.) reproductive opportunities were organized collectively and were allocated to individuals who have made demonstrable contributions to the survival of the group. Judgments of worthiness of higher social rank were often based on ritual tests of skills. The outcome determined an individual's local status and access to reproductive opportunities (Fisher 1999). In contrast,

Fisher pointed out European societies were marked by an inversion of the relationship between social position and fertility. Although the wealthy could afford larger families, their genetic lineages were frequently extinguished as a result of low fertility. Among the poor, fertility levels were much higher but economically unsustainable. Moreover, fertility rates were closely scaled with social position. Individuals striving for higher social ranks delayed reproduction much later into their lives or invested more in the well-being of close genetic relatives rather than themselves. Fisher (1999) argued that sociological factors, not genetic factors, were pushing reproductive efforts of higher-status individuals to levels below an adaptive threshold.

Naturally, Fisher approached his model of the social selection and the inversion process in the same way he approached his model of natural selection. He decomposed fitness into two components: *directed agencies* and *undirected agencies* of evolution. Directed agencies include both genetic and environmental factors whose cumulative effects create optimal conditions for genetic evolution and, hence, maximize variation of fit genotypes within a population. Undirected agencies deteriorate the environment of genetic evolution and reduce the reproductive value of the individual and, over time, the population (Fisher 1999). Undirected agencies include harmful mutations, increased competition from internal and external groups, and temporal and spatial changes which bring about scarcity in available resources. Fisher stated that even if an organism is highly adapted to its environment undirected agencies will persistently challenge the fitness of the organism.

Social structures can function as directed or undirected agencies. According to Fisher, elements of “savage” and “barbarous” societies functioned as directed agencies of evolution. These societies had their share of problems. However, they achieved organizational forms and practices that tended toward optimization of the connections between genetic qualities, social rank, and fertility. On the other hand, modern European societies lost this quality at some point in their industrial evolution. Industrialization had

overcome some problems inherent in collectively oriented societies, but it presented a different set of “sociological difficulties” which threaten individual and population fitness. Inversion of the relationship between social rank and fertility resulted from three factors: (1) the economic organization of industrialization increased the cost of parenting; (2) the value of wealth as an indicator of fitness became greatly exaggerated; and (3) individual reproductive and mating preferences adapted to local cultural conditions.

Industrialization has increased the costs of parenting as a result of the individuation of property and wealth accumulation. This, in turn, generated resource scarcity to the degree that an individual must make tradeoffs between time invested in wealth accumulation and time invested in offspring. Since industrialized societies lacked ritual tests of an individual’s biological qualities, fitness indicators had become more subject to cultural manipulation. Cultural indicators might impose minimal or no genetic costs to the individual displaying the indicator. In a speech to the Eugenics Education Society, Fisher argued that the wealth had become greatly exaggerated in its value as an indicator of an individual’s true genetic fitness. Wealth, like many other cultural indicators, can be easily acquired through non-genetic inheritance. Individuals can simply imitate or mimic the behaviors of the wealthy. Hence, possession of the indicator (wealth), because of biasing cultural influences, became decoupled from the gold standard of genetic fitness. Fisher likened the process to runaway sexual selection:

[This form of social selection] has, however, all of the dangers noted in the case of sexual selection, of running into extravagance; for the standards of taste will necessarily be modified, step by step, with the qualities to which preference is given, and it may indeed, be that some of the virtues which appeal most to our imagination are more of the nature of ornaments than serviceable moral ideals. (Fisher 1999, p. 251)

Eugenics and the Question of Race

Fisher had professional ties to eugenics movement of the early twentieth century. His published

comments were mostly in broad agreement with philosophy of eugenics and seemed sympathetic, at least, to nationalist agenda it embodied. In a speech given to the Eugenics Education Society, Fisher stated:

Eugenics is not inherently associated with nationalism; but in the world of nations, as we see it, nationalism may perform a valuable eugenic function. The modern nation is a genetic, a territorial, and an economic organism, and the modern tendency is to emphasise its essential unity, the community of interests of its individual members; European nations are grouping themselves along ethnic lines, and the individual finds himself more and more closely engaged in serving the greater interests of his race. (Fisher 1914, p. 310)

But there is also a complexity in his views (Louçã 2009). While Fisher saw the virtues of a eugenics program, he also recognized its limitations. In the same speech, he presented the “specialization problem.” Fisher believed a eugenics program should strive to improve environmental conditions as much as it might focus on improvement of the genetic stock in a population. He proposed that any effort to build stock must consider that the expression of traits is the result of an interaction between genes and environment (Fisher 1914). But this, Fisher explained, begged the question of what type of an environment should be built. Should a eugenics program strive to create an environment which leads to the rapid evolution of individuals with highly specialized skill sets as seen in other cooperative species? Or, should a eugenics program strive to evolve individuals with generalized skills? Fisher did not provide a resolution, but he clearly believed the optimal strategy to ensure the long-term survival of any civilization would encourage “versatility” in traits in the same way evolution favors biological diversity in populations of species.

In a similar way, Fisher held views on race which, on the one hand, aligned with eugenicist arguments but also stood in stark contrast to them. In 1952, the United Nations’ Educational, Scientific and Cultural Organization (UNESCO) wrote a statement on race which would drive policy. The statement was intended as a response to destructive consequences of racial prejudice wrought in Nazi Germany and elsewhere. UNESCO sought

to “launch a campaign against race prejudice and extirpate this most dangerous of doctrines” (UNESCO 1952, p. 5). UNESCO proclaimed the idea of race is essentially a social construction with very little biological significance. Furthermore, intelligence and other desirable traits varied within groups as much as between racial groups. Before publishing the statement, UNESCO invited criticisms from 96 scientists representing various disciplines in the natural and social sciences. Fisher was among them. He agreed with the intentions of UNESCO but was critical of the denial of the genetic basis of racial group differences in behaviors and intelligence. He believed part of the UNESCO statement should be revised to read:

Available scientific knowledge provides a firm basis for believing that the groups of mankind differ in their innate capacity for intellectual and emotional development. (UNESCO 1952, p. 55)

Fisher’s criticisms are placed in the same group of scientists such as Carleton Coon, whose work was heartily embraced by white supremacy groups in the United States (Jackson 2001). However, Fisher’s earlier writings clearly show he did not support the core tenets of white supremacists’ philosophy. Sixteen years prior to the publication of the UNESCO report, Fisher was critical of studies of racial group differences because researchers would exaggerate the meaning of the concept of statistically significant difference. He wrote:

It must be stressed that the test of significance calculates a probability; it does not calculate a racial difference. (Fisher 1936, p. 4)

In *The Genetical Theory of Natural Selection*, Fisher countered prevailing theory that miscegenation would lead to the erosion of civilized societies in Europe. He aimed his critique specifically at a theory proposed by Arthur Gobineau (Gobineau and Collins 1915), which stated: (1) there are three races; (2) the white race is superior among them; (3) inequalities between races were unrelated to social factors; and (4) racial differences in intellectual capacity were entirely due to biological factors (Gobineau and Collins 1915). Gobineau reasoned racial mixing would deplete the genetic stock of the

white race and, thereby, cause the decline of white civilization. Fisher (1999) criticized Gobineau on logical and genetic grounds. Logically, Fisher argued it does not make sense that a supposedly “biologically superior” race can be so easily taken out of existence by a supposedly “biologically inferior” race. On genetics, Gobineau’s argument ignored Mendelian effects of racial mixing and failed to consider the vital importance of biological diversity within a population. Fisher wrote:

The general consequences of race mixture can be predicted with confidence. . . . If the races and their descendants intermarry freely, the factors which are inherited independently will be recombined at random; each person if mixed race will resemble one parental stock in respect of some factors, and the other stock in respect to others. Their general characteristics will therefore be intermediate, but their variability will be better than that of the original races. . . . [T]he ultimate effect of mixture will be the production of a race, not inferior to those from which it sprang, but rather superior to both, in so far as the advantages of both can be combined. (Fisher 1999, p. 238)

Fisher firmly believed that the lessons of science and the knowledge acquired through science should be used toward building healthier environments and healthier populations. In part of his speech to the Eugenics Education Society, he offered this appeal:

From the individual point of view our duty is, I think, clear; like all healthy philosophies, eugenics urges us to simplify our lives, and to simplify our needs; the only luxury worth having is that of a worthy human environment. We must be ready to sacrifice social success, at the call of nobler instincts. And, even as regards happiness, has any better way of life been found than to combine high endeavour with good fellowship? We require a new pride of birth, in that whatever valuable quality we show really goes to establish the quality of the family; and a new confidence in our instinctive judgments of human worth. (Fisher 1914, p. 313)

Roy Baumeister

Dianne M. Tice
Brigham Young University, Provo, UT, USA

Overview

Roy F. Baumeister is one of the most widely published and highly cited social psychologists in the world. He is known for his work on many aspects of the self and human nature. As of 2018, he is currently a professor of psychology at the University of Queensland, in Brisbane, Australia.

Honors and Awards

Although a comprehensive list of honors and awards is not practical in this space, a few of Baumeister's most noteworthy honors are included. In 2015, Baumeister was inducted into the American Academy of Arts and Sciences. That same year, he and his co-author Mark Leary were awarded the Scientific Impact Award from the Society of Experimental Social Psychology for a paper they had written titled "The Need to Belong" (Baumeister and Leary 1995). In 2013, Baumeister was awarded the highly prestigious William James Fellow Award for lifetime contributions to psychological science from the Association for Psychological Science. This is the highest honor that the Association for Psychological Science bestows. Also in 2013, the Association for Psychological Science announced

that the Baumeister et al. (2003) article on self-esteem that was published in *Psychological Science in the Public Interest* was the most frequently cited article in the entire history of all journals published by the Association for Psychological Science. In 2012, Baumeister was awarded the Distinguished Lifetime Career Contribution Award from the International Society for Self and Identity, and in 2011 he was awarded the Jack Block Award for Distinguished Contributions to Personality Psychology by the Society for Personality and Social Psychology. In 2007 he was awarded the Distinguished Service Award for the Society for Personality and Social Psychology and in 2008 the Lifetime Achievement Award from the International Network on Personal Meaning.

Research Activity

Baumeister has published a wide variety of topics in the fields of social psychology, personality, evolutionary psychology, developmental psychology, social clinical psychology, social cognitive psychology, sport psychology, and many others. A sampling of the topics covered in Baumeister's research includes the self, belongingness and rejection, consciousness, human sexuality, human nature, suicide, psychometrics, economics, gender issues, emotion, motivation, free will, choking under pressure, UFO abductions, and sex, drugs, and rock and roll.

As can be seen from the partial list of topics that he has researched, Baumeister has always had a strong interest in interdisciplinary research and has often focused on the interpersonal perspective in his work. He has been a strong proponent of the importance of studying behavior in the behavioral sciences, rather than relying solely or even mainly on self-reports and responses to computerized stimuli to dominate our view of the human psyche.

Much of his work has centered on the psychology of the self, identity, and human nature. As of 2017, he has a total of over 630 publications, with over 300 peer-reviewed journal articles and 35 books. Twelve of his articles have

appeared in the highly esteemed journals *Psychological Review* and *Psychological Bulletin* (e.g., Baumeister and Masicampo 2010; Baumeister et al. 1996), and over 50 of his articles have appeared in the *Journal of Personality and Social Psychology* (e.g., Baumeister 1984; Baumeister et al. 1990, 2002).

In addition to being highly prolific, Baumeister's work has had a huge impact on the fields in which he publishes, as demonstrated by the numerous citations of his work. As of the end of 2017, Baumeister's work has been cited over 143,000 times. In 2017 alone, his work was cited 15,214 times. Put another way, every day there is new scientific work published that lists some of his publications in its References section – indeed that happens on average over 41 times each and every day of the year. Baumeister has 29 papers that have been cited at least 1000 times as of 2017.

In recent years scientific productivity has increasingly been measured by the h-statistic, which is the highest number (H) for which the scientist has H publications that have each been cited H times. Note that doubling the statistic requires far more than doubling one's success. An H of 20 signifies 20 articles cited 20 times each, while an H of 40 indicates 40 articles cited 40 times each. Baumeister's h-index in 2017 was 157, and his i10-index is 446, making him one of the most cited and influential social psychologists in the world.

Areas of Research of Special Interest to Evolutionary Scientists

Although Baumeister has published in many different areas of psychology over the course of his career, a few of the topics he has covered may be of special interest to evolutionary psychologists. These topics include human sexuality, the need to belong, the cultural animal, self-regulation, suicide, and the idea that bad things have a stronger impact on us than good things.

Baumeister's human sexuality contributions that have had the greatest impact (in terms of citation rates) include his review and theory

papers on the topics of gender differences in sex drive, erotic plasticity, and sexual economics.

In 2001, in collaboration with Kathleen Catanese and Kathleen Vohs, Baumeister published an article reviewing the literature on gender differences in strength of sexual motivation (Baumeister et al. 2001b). After reviewing a large number of papers with different studies and different measures of sexual motivation, the authors observed that men showed stronger sexual motivation, as demonstrated by findings that men are more likely than women to have spontaneous thoughts about sex, greater frequency and variety of sexual fantasies, greater desired frequency of intercourse, greater desired number of partners, more masturbation, and greater liking for various sexual practices. They also observed that men were more likely to initiate (and less likely to refuse) sex, were more likely to make sacrifices for sex, and in other ways seemed to display more frequent and more intense sexual desires than women. In their review of the literature, they found no evidence from any measure indicating that women had stronger sexual motivation than men, although they cautioned that their findings should not be generalized to other constructs such as sexual or orgasmic capacity, enjoyment of sex, or extrinsically motivated sex. The authors concluded from their review that the male sex drive is stronger than the female sex drive. As of the end of 2017, this article has been cited over 780 times, indicating that it is a classic article in the field.

Drawing on the idea that men have a stronger sexual motivation than women, Baumeister (2000) suggested that the strength of men's motivation for sex would decrease the plasticity or flexibility of the sex drive in men as compared to women. Baumeister coined the term "erotic plasticity" (Baumeister 2000) to refer to the idea that the female sex drive is more malleable and flexible than the male sex drive in response to socio-cultural and situational factors. After reviewing the literature, Baumeister (2000) concluded that female sexuality exhibited more flexibility than male sexuality across three dimensions. Firstly, individual females exhibited more variation across time in their sexual behavior than did males. Secondly, female sexuality was more

responsive than male sexuality to sociocultural variables. Thirdly, women showed a lower level of consistency between their sexual attitudes and their sexual behavior than men did, suggesting that outside influences could lead to greater sexual flexibility in females compared to males. Baumeister (2000) discussed possible explanations for this greater erotic plasticity in women compared to men, including the idea that women have a milder innate sex drive, allowing women's sexual behaviors to be more responsive to sociocultural and situational factors. As of the end of 2017, this article has been cited over 850 times, indicating that it is also a classic article in the field.

A third paper on human sexuality with almost 400 citations by the end of 2017 is the paper Baumeister authored with Kathleen Vohs on sexual economics (Baumeister and Vohs 2004). In this paper, the authors compared the heterosexual community to a marketplace in which men seek to acquire sex from women by offering other resources in exchange for sex. In other words, sexuality was compared to an economic market in which men are buyers and women are sellers of sexuality. The paper examines many behaviors that are consistent with such a view of sexuality as an economy, such the fact that most societies place higher value on women's sexuality in issues such as virginity, fidelity, and chastity than they do on men's sexuality. In Baumeister and Vohs's (2004) interpretation, economic principles such as supply and demand, competition and collusion among sellers, and other economic factors will affect the "price" that women can ask and that men will pay for sex. In their explanation, price refers not only to the price of prostitution but also the price that must be paid for marriage or divorce, courtship, or infidelity and the finding that women's sexuality has what economists refer to as value but men's sexuality has no such marketplace value. The authors discuss how describing human sexual exchanges as economic exchanges with men as buyers and women as sellers can help explain various factors including the repression of women, the suppression of female sexuality, abusive relationships, rape, and changing norms and sexual attitudes.

In addition to work on human sexuality, other works by Baumeister may hold special interest to evolutionary psychologists. In conjunction with the eminent social psychologist Mark R. Leary, the paper published on the need to belong (Baumeister and Leary 1995) is Baumeister's most highly cited and influential paper, with over 15,000 citations by the end of 2017. The authors described the universal human need to belong, expanding and differentiating it from the older, simpler notion of need for affiliation. They reviewed the existing literature, developed the theory, and determined that the need to belong was a powerful, fundamental, and extremely pervasive human motivation. In addition to proposing the universal need to belong, the authors also developed an exhaustive description and criteria for what is required for something to be classified as a fundamental human motivation, and it is this description and classification that is of special interest to many evolutionary scientists.

One of Baumeister's publications most directly relevant to evolutionary science is his book *The Cultural Animal: Human Nature, Meaning, and Social Life* (Baumeister 2005). In *The Cultural Animal*, Baumeister makes the case that humans evolved for culture. Rather than being merely "the social animal," a better sobriquet for humans is "the cultural animal." Although the idea of humans as social animals is correct, humans are not the only, nor perhaps even the most, social animal. What may be much more distinctive about humans and account for our evolutionary success is the fact that we evolved to take advantage of the ability to create and participate in culture. Other animals may show rudiments of culture, but we are the only species to use culture to such an extent as an evolutionary strategy. The main idea of the book is that human nature, and the individual human psyche, was designed by evolution to enable humans to create and sustain culture.

In another area of research of interest to evolutionary scientists, Baumeister has published numerous articles and books on self-control with his colleagues (e.g., Baumeister et al. 1998). Self-control has been shown to be important to evolutionary success in a variety of species

including humans. Baumeister and colleagues' work on willpower, ego depletion, the mechanisms underlying self-control, and other aspects of self-control have added extensively to the literature on self-control and its importance to human nature. Many of these books and articles on self-control have very high citation counts, and his book *Willpower: Rediscovering the Greatest Human Strength*, written with John Tierney, became a *New York Times* bestseller and spent over a month on Amazon's top 100 list.

Suicide has often posed somewhat of a problem for evolutionary researchers seeking to explain human behavior because most evolutionary accounts emphasizing survival and reproduction have difficulty explaining evolutionary benefits or even explanations for suicide. Baumeister's (1990) theory of suicide as an escape from self-awareness (as part of his research on escape-from-self mechanisms including binge eating, sexual masochism, alcoholism, and other behaviors as escape from self-awareness) can explain some elements of a behavior that runs contrary to our usual motivations to survive and reproduce. Baumeister's (1990) article on suicide as an escape from the self has had over 1500 citations as of the end of 2017.

Baumeister coined the term "bad is stronger than good" to describe the work published with colleagues (Baumeister et al. 2001a) on the idea that bad things exert a stronger influence on us than good things. Their paper examined the evolutionary advantage of bad being stronger than good. This paper has over 4900 citations as of the end of 2017. Baumeister is currently (2018) working on a book on this topic with his co-author John Tierney.

Protégés

One estimate of a scholar's impact is the protégés that he or she has mentored. Baumeister has an impressive list of graduate and postdoctoral students that he has mentored that have gone on to have made significant contributions to the field of psychology. As of 2017, his full list of protégés comprises 19 postdoctoral fellows and 27 Ph.D.

students in social psychology, as well as a couple of additional students in clinical and industrial psychology. Thus far, every single one of Baumeister's protégés has gone on to an academic job after working with him.

Educational Background

Baumeister received his bachelor's degree in 1974 from Princeton University, where he worked with Joel Cooper. During his undergraduate years, he spent a year abroad at the University of Heidelberg where he studied philosophy. After receiving his M.A. from Duke University in 1976, he moved back to Princeton when his graduate advisor, Edward E. Jones, accepted a job there. He received his Ph.D. from Princeton University in 1978.

Employment History

After receiving his Ph.D., Baumeister moved to the University of California at Berkeley for a 1-year postdoc in sociology. In 1979 he moved to Case Western Reserve University where he held a faculty position until 2003. From 2003 to 2016, he was the Eppes Eminent Professor of Psychology at Florida State University and in 2016 moved to the University of Queensland in Australia.

Baumeister has traveled extensively during his career, taking advantage of sabbaticals and leaves of absence to work as a visiting professor in numerous locations. In 1986–1987, he had a visiting position at the University of Texas at Austin, and in 1991 he was a Visiting Professor at the Max Planck Institute in Munich, Germany. In 1993 he spent his sabbatical at the University of Virginia, in 2001 as a Fellow at the Center for Advanced Study in the Behavioral Sciences at Stanford

University, and in 2009 at the University of California, Santa Barbara. From 2010 to 2015, he served as a Special Professor at the VU University, Amsterdam, Netherlands, where he taught graduate classes every year. In 2013 he spent a year as a Research Fellow at the Russell Sage Foundation in New York City, and in 2014 he served as a Distinguished Adjunct Professor at the King Abdulaziz University in Saudi Arabia.

Definition

Paleartic lekking sandpiper that breeds across Northern Eurasia and winters in Europe, Africa, South Asia, and Australia.

Introduction

The Ruff is a member of the *Scolopacidae* family representing the genus *Philomachus*. The genus name means “combative battle lover” reflecting the aggressive male-male competition during the breeding season in this lekking bird. Some taxonomic authorities have assigned the species to the genus *Calidris* (Van Gils et al. 2016). Ruffs breed in coastal and inland wetlands and tundra habitat across Northern Eurasia (Bird Life 2015; Van Gils et al. 2016).

General Biology

The Ruff is a sexually dimorphic species; males are 10–70 % larger than females (Van Gils et al. 2016). Ruffs have a strongly female-biased sex ratio that is already apparent in juveniles; males only comprise 34–40 % of the population (Jaatinen et al. 2010). This sex bias may have contributed to the evolution of the highly polygynous mating system. The oldest known Ruff in the wild reached an age of more than 10 years based on banding data (Van Gils et al. 2016). Ruffs are insectivorous during the breeding season but may also feed on plants including rice seeds during wintering.

Total population is estimated to be above two million individuals. The conservation status is “least concern” although the range is contracting because of habitat degradation caused by intensified agriculture meaning that populations especially in Europe are likely declining (Bird Life 2015).

Ruffs are migratory birds. Migration schedules are different for males and females. Adult males generally migrate earlier than adult females and juveniles leave the breeding grounds last. Females overwinter further south than males, probably

because males need to arrive early on the breeding grounds to obtain a position on the lek. Some Ruffs overwinter in Western Europe, although the majority of Ruffs will winter in Africa (Van Gils et al. 2016). Other significant wintering locations are in Southeast Asia and Australia.

Adult Ruffs molt up to three times a year. After the breeding season they will acquire a dull grey brown winter plumage through a complete post-breeding molt that lasts until mid-autumn (van Rhijn 1991). Within 2 months of completing the postbreeding molt Ruffs molt into more variable high contrast plumage that serves as a breeding plumage for females and prenuptial plumage for males. Males gain their breeding ornaments during a nuptial moult on the late stages of spring migration. The full breeding plumage of males includes the characteristic a neck ruff of extended feathers, which gave the species the name, colored head tufts, and facial wattles. The legs of males and females will take up a vibrant orange coloration during the breeding season whereas during the nonbreeding season they are green to brown.

Breeding

From April to July, Ruffs breed in open areas in Arctic, subarctic, and temperate zones of Eurasia. Ruffs are able to breed in the second calendar year in captivity although young males will rarely be able to obtain a place on a lek and search for vacant lek positions as marginal males. Ruffs are polygynous and males gather in leks consisting of typically 4–9 displaying males who compete aggressively for matings (van Rhijn 1991). The male breeding plumage is highly variable; barely two males will resemble each other. Ornament feathers of ruff and head tufts can take up a range of colors from white, ivory, straw, rusty brown to black with regular, irregular barring or spots of different size. Plumage is not associated with reproductive success, rather it may aid individual recognition replacing acoustic communication, since Ruffs are barely vocal (Lank and Dale 2001). This recognition is thought to reduce repeated exhaustive fights between males on leks once a dominance hierarchy has been established.

The reproductive success is heavily skewed among males, the dominant male on the lek will mate with most females (van Rhijn 1991). Females frequently mate with more than one male and provide all parental care whereas the male only contributes the sperm to the joint offspring. Females will often nest near leks in a well-concealed nest where they usually lay four eggs that hatch after 20–23 days. Chicks usually fledge with 25–28 days although the female may leave the young a few days before fledging (Van Gils et al. 2016).

Alternative Reproductive Tactics

Ruffs exhibit one of three discrete alternative mating strategies, which have the strongest impact on male appearance and behavior. The majority of male Ruffs (~85 %) are “Independents” (also called “Residents”). They try to obtain a place on a lek where they then display aggressively and fight other independent males to mate with visiting females. Independents are characterized by darker breeding plumage ornaments (van Rhijn 1991). They also comprise the largest morph (Lank et al. 2013). By contrast, “Satellite” males (~14 %) are nonterritorial, paler ornamented birds of intermediate size. They show submissive behavior towards lekking independents and do not fight aggressively for matings (van Rhijn 1991). However, they are the “kingmakers”: by forming an alliance with an independent territory owner, they make this male more attractive to females. Satellites themselves receive no obvious direct reward from their ally, but they use the confusion that arises during frequent fights on leks to mate with visiting females. The third morph (“Fæders”) has no male breeding ornaments and does not display (Jukema and Piersma 2006; Küpper et al. 2016). It is the smallest and rarest morph (~1 %). Fæder males travel with females and, like Satellites, they are nonterritorial and nonagonistic. They remain proximal to displaying males and use their female mimicry to rapidly sneak copulations when females solicit. Avian studies demonstrated that the differences between morphs are irreversible and encoded by a

simple genetic dominant/recessive mechanism (Lank et al. 1995, 2013). Fæders and Satellites carry specific variants of a large dominant chromosomal inversion that corresponds to ~20 % of chromosome 11 (Küpper et al. 2016; Lamichhaney et al. 2016). The inversion is lethal when homozygous meaning that Fæders and Satellites require a copy of the ancestral Independent variant to survive. It contains 90–125 genes among them several candidate for differences in aggressive behavior and plumage ornaments (Küpper et al. 2016; Lamichhaney et al. 2016). The inversion has probably arisen first in Fæders about four million years ago whereas the Satellite variant has arisen through subsequent rare hybridization event between Independent and Fæder chromosomal variants about 500,000 years ago (Lamichhaney et al. 2016) (Fig. 1).

Conclusion

The Ruff is a classic ecological model system of sexual selection characterized by high intraspecific diversity in morphology, plumage, and behavior. Ruff populations have three discrete morphs that are strongest expressed in males although both males and females carry morph-defining genetic variants. The currently large populations of this migratory shorebird are declining and may be further impacted by ongoing habitat changes caused by global warming.

Rule Violations Checked If High Status

Definition

The idea that individuals of high standing in a social hierarchy check for and remember rule violations of relatively lower-status individuals.

Introduction

The ability to detect rule violations is often seen as necessary to the development of social contracts. Specifically, cooperation and reciprocity are typically understood to depend on the ability of group members to identify and penalize social rule violations. In this regard, it is crucial to detect and remember cheaters, those who (intentionally) violate social rules. Importantly, in communal species such as our own, the social environment is governed, in part, by a social hierarchy wherein some members occupy higher levels of status. In this context, higher-status individuals have been hypothesized to maintain their priority access to resources (e.g., food, mates) by increased detection and memory of lower-status cheaters (Cummins 1999). Evidence in support of this claim is reviewed as well as investigations indicating that social status may not have an impact on cheater detection. In addition, insights from the broader domain of cheater detection, unconcerned with social status, are detailed, indicating that identification, memory, and penalization of cheaters is a complex process in need of continued study. Finally, the various methods of measuring social status in humans are noted, providing avenues for future exploration into the role of social status in cheater detection.

High-Status Individuals and Cheaters

While there are numerous accounts in social animals, such as primates, investigating and supporting the idea that high-status individuals are more likely to check for and detect cheaters of lower-status there have been relatively few empirical investigations in humans. Indeed, it appears the oft-cited Cummins' (1999) is the only published work empirically and explicitly investigating the effect of social status on checking for and detecting cheaters in humans (although see Fiddick and Cummins 2001 for discussion of conceptually similar studies demonstrating mixed results). In specific, Cummins conducted two experiments wherein the relative

status of subjects was manipulated in a Wason Card Selection Task. In the first experiment, subjects had to test compliance with a college dormitory rule (i.e., if someone is assigned to tutor a study session, that person is required to tape record the session) and were split into four conditions:

High-status: Subjects engage the task as a high-status individual (Resident Assistant) checking on lower-status individuals (Students).

Low-status: Subjects engage the task as a Student checking on Resident Assistants.

High-status Equal: Subjects engage the task as a Resident Assistant checking on fellow Resident Assistants.

Low-status Equal: Subjects engage the task as a Student checking on fellow Students.

In all conditions, save for the High-status condition, 15–20 % of subjects used a cheater detection strategy. In contrast, 65 % used a cheater detection strategy when engaging the task as a high-status individual checking on lower-status individuals. Thus, subjects were significantly more likely to look for cheaters when checking on individuals who were of relatively lower status. The second experiment was identical to the first with one important change: in this version, subjects were initially asked to engage the task from a high-status perspective and then switch to a low-status perspective. This ordering was reversed for half the participants and a distraction task was used between perspectives to decrease the chance of carry-over effects. When subjects engaged the task as a low-status individual first, 41 % used a cheater detection strategy. After switching to a high-status position, this percentage increased significantly to 65 %. Thus, in the same person a cheater detection strategy was more likely to be employed when they were a high-status person investigating low-status individuals. When taking the High-status perspective first, 50 % used a cheater detection strategy and 40 % continued to use this strategy even after being placed in the lower-status position. This was a nonsignificant decrease and was taken to indicate that once cheater detection is engaged in a high-

status position, it is difficult to disengage regardless of any change in relative social status.

In contrast to Cummins, which directly assessed checking for cheaters by high-status individuals, most investigations into this effect have relied on memory paradigms focused on pictures of people's faces. In these tasks, subjects are typically presented with pictures of faces alongside descriptions of cheating, trustworthy, or neutral acts and tested for their memory of these faces after a time interval (e.g., a few minutes to a week). The central idea being that individuals using a cheater detection strategy should have better memory for faces matched with descriptions of cheating (i.e., cheaters). When social status is manipulated in these tasks, it is typically done via the job title given in the character descriptions (e.g., low-status job: baseball game vendor, high-status job: bishop). Using this technique, Mealey and colleagues (1996) found, in line with Cummins' results, significantly better memory for faces of low-status cheaters compared to high-status or noncheaters. These results, along with Cummins', are typically cited as evidence that high-status individuals are more likely to detect and remember low-status cheaters.

Despite the widespread citation of Cummins and Mealey et al.'s findings, recent investigations have noted areas of concern and have failed to replicate key status-related results. In this regard, Mealey and colleague's findings have been the main focus of examination, with apparently no studies attempting to replicate Cummins' findings. For example, Mehl and Buchner (2008) detail several areas of concern regarding the methods reported by Mealey et al. noting that the behavior and character description stimuli were not fully reported and that those descriptions that were reported differed in length and amount of detail, which may make some stimuli easier to remember. In a similar vein, Barclay and Lalumière (2006) comment that cheaters in Mealey et al.'s stimuli may be more salient, and thus more memorable, because their actions, in comparison to cooperators', are more intense, with cheaters not only breaking small social rules but also engaging in more threatening or

physically dangerous behaviors such as robbery or child molestation.

Beyond these concerns, and more importantly, six experiments across three studies have failed to replicated Mealey et al.'s results regarding high-status individuals (i.e., experiments 1 and 2 in Barclay and Lalumière 2006; experiment 4 in Buchner et al. 2009; experiments 1, 2, and 3 in Mehl and Buchner 2008 – experiment 3 did find better memory for faces associated with high-status professions, but there was no interaction with cheating or trustworthy behavior). These studies not only attempted replications they also sought to control for and assess potentially confounding variables such as sex of participant, sex of the face used in the stimuli, attractiveness and likability of the faces used, and time interval between initial display of the stimuli and memory testing. Overall, these results indicate that Mealey et al.'s findings may be singular or that there are influences in the original finding that are currently unaccounted for. Given this, and the lack of replication of Cummins findings, evidence to-date is equivocal that higher-status individuals preferentially check for or have greater memory for lower-status cheaters.

Complexities in Cheater Detection

The discussion of whether social status impacts cheater detection is necessarily couched within the much larger and historic debate on whether humans possess a cognitive mechanism specifically for detecting cheaters. While not able to engage this broader debate in full, the studies using the memory paradigm detailed in Mealey et al., although unable to confirm the impact of social status on cheater detection, do indicate that detecting cheaters is a highly complex process. For example, Chiappe et al. (2004) found that people see it as subjectively more important to remember cheaters than cooperators and that this was more evident when there were larger amounts of resources involved. They also noted that cheaters were looked at longer than cooperators,

that subjects were more likely to remember the faces of cheaters, and that cheating behavior was more likely to be remembered. Put another way, Chiappe and colleagues found that cheaters are remembered more and that individual (i.e., subjective importance and visual attention) and contextual variables (i.e., amount of resources involved) may moderate this effect.

In contrast to these results, Buchner and colleagues (2009), across four separate experiments, were unable to detect evidence of improved memory for cheaters despite also investigating the impact of various stimuli features such as attractiveness, likability, different intervals of memory retention, and whether the behavior described in the stimuli was exceptional or ordinary. They did, however, find evidence of improved memory for the conditions or features under which people did cheat, also known as source memory. In other words, people did not show improved memory for cheaters, but did show improved memory for the situations or context the cheaters acted in. Lastly, and importantly, Barclay (2008) demonstrated that the ability to remember cheaters or cooperators may be related to their rarity. Specifically, in this study, cheaters were remembered best when they were rare but worst when they were common, with the same being true of cooperators. These results suggest that people remember whatever behavior is rarest regardless of whether that behavior is cheating or cooperating. Overall, this collection of results demonstrates that cheater detection is shaped and dictated by a host of individual and situational variables.

Moreover, the often implicit but sometimes explicit assumption is that cheaters, especially lower-status cheaters, will be punished or penalized when detected. In stark contrast to this, Fiddick et al. (2013) has documented the cross-cultural presence of *noblesse oblige*, the tendency or obligation of higher-status individuals to be more tolerant of and generous to lower-status individual's, even if they cheat. Thus, even if status does not impact the detection of cheaters, it may effect the actions taken once they are detected.

The Many Faces of Status

The evidence so far indicates, in a somewhat contradictory fashion, that cheater detection may not be influenced by social status in humans but that it may be influenced by a host of other individual and situational variables. In this context, it is important to note the way social status has been manipulated or investigated up to this point. Specifically, in all of the studies described here status was manipulated via occupation or income. In contrast to this, literature and research on social status in humans indicates that an individual's position in the social hierarchy is determined by a variety of connected, yet independent, constructs, such as power, socioeconomic status, dominance, prestige, influence, and leadership (Blader and Chen 2014). Adding to the complexity of this picture is the fact that while social status is often discussed as a dispositional trait, it is also highly situational, such that an individual may be of high status in one environment (e.g., friend group or family) but low status in another (e.g., occupation). In this regard, the concepts and methods used to assess the impact of status have been relatively narrow.

Conclusion

Evidence in humans is currently equivocal as to whether high-status individuals display an increased detection or memory of lower-status cheaters. At the same time, the methods used to investigate the effect of status have been relatively narrow and numerous studies have demonstrated the impact of various individual and situational variables on cheater detection. Further clarity on the influence of status on cheater detection could be achieved through boarder investigation into the numerous ways social status is determined in human hierarchies and by more diverse methods of inquiry.

Definition

The idea that individuals of low standing in a social hierarchy do not check for or remember rule violations of relatively higher status individuals.

Introduction

The development of social exchanges, such as cooperation and reciprocity, is typically seen to be dependent, in part, on the ability to detect and remember the violation of social contracts. In this regard, it is crucial to be able to discover and identify cheaters, those who (intentionally) violate social contracts. Importantly, by their very nature social exchanges and cheating operate within social systems created by social species. Like many social species, ours has developed a social hierarchy wherein some members hold higher standing than others. In this context, it has been suggested that lower status individuals are less likely to detect, remember, and penalize cheaters of relatively higher status (Cummins 1999). Evidence in support of this claim is presented as well as results from recent studies which call this account into question. In addition, the definition of social status in humans is explored, providing ways of further clarifying the role of status in cheater detection. Finally, the ability of lower status individuals to enforce social rules is explored as a potentially important variable to

consider when exploring social status and cheater detection in humans.

Low-Status Individuals and Cheaters

In nonhuman animals, there is a wealth of literature supporting the idea that lower status individuals are less likely to detect, or at least penalize, cheating in higher status individuals. In humans however, empirical data are sparse. Indeed, it appears that the oft cited Cummins' (1999) is the only published work to empirically, and directly, investigate this effect in humans (although see Fiddick and Cummins 2001 for discussion of conceptually similar studies demonstrating mixed results). In this work, Cummins, using the Wason Card Selection Task, had participants test compliance with a college dormitory role (i.e., if someone is assigned to tutor a study session, that person is required to tape record the session), with relative status manipulated via four groups:

High-Status: Subjects engage the task as a high-status individual (Resident Assistant) checking on lower status individuals (Students).

Low-Status: Subjects engage the task as a Student checking on Resident Assistants.

High-Status Equal: Subjects engage the task as a Resident Assistant checking on fellow Resident Assistants.

Low-Status Equal: Subjects engage the task as a Student checking on fellow Students.

In the first experiment, participants were simply placed into one of the four groups and their actions were tallied. Here, Cummins found that participants in the high-status group used a cheater detection strategy about 65 % of the time. In contrast, those in the remaining conditions, including the low-status condition, used a cheater detection strategy only 15–20 % of the time. In other words, low-status individuals were unlikely to engage in detection of cheaters when checking on higher status individuals, at least relative to high-status individuals checking on those of lower status. In the second experiment, Cummins employed the same task but had

participants answer from both a high- and low-status position, with the order reversed for half the sample and a distraction task between perspectives. In this version of the task, participants starting from the low-status position used a cheater detection strategy 41 % of the time, which increased significantly to 65 % after switching to the high-status position. In contrast, 50 % of participants used a detection strategy when starting from the high-status position, with this dropping a nonsignificant amount to 40 % after switching to the lower status position. Like the first experiment, these results were taken to indicate that lower status individuals were less likely to detect cheaters of higher status.

In contrast to Cummins investigation, which directly evaluated the impact of social status on cheater detection, most investigations into this effect use tasks focused on whether individuals can remember the faces of cheaters. In these tasks, participants are typically presented with pictures of people faces along with descriptions of cheating, trustworthy, or neutral behaviors. Then, after a predetermined time interval, usually ranging from a few minutes to a week, participant's memory is tested, with the key idea being that individuals using a cheater detection strategy should have better memory for cheaters' faces. When social status is manipulated in these tasks, it is typically done via the job title given in the character descriptions (e.g., low-status job: baseball game vendor, high-status job: bishop). The most well-cited study using this technique is Mealey et al. (1996), which found, after a week-long interval, better memory for *low-status* cheaters in comparison to high-status or non-cheaters. These results mirror Cummins' and can be seen as providing evidence that low-status individuals are less likely to attend to or remember cheating by relatively higher-status individuals.

Despite being widely cited, however, recent investigations have noted areas of concern and have failed to replicate Mealey and colleague's results (there do not appear to be published attempts to replicate Cummins findings). Specifically, Barclay and Lalumière (2006) note that the cheating behavior in Mealey et al.'s stimuli includes instances of more threatening or

physically dangerous behaviors, such as robbery and child molestation, which may make cheaters easier to remember compared to cooperators. In a similar vein, Mehl and Buchner (2008) note that the behavior and character descriptions used in Mealey et al. were not fully reported and that those descriptions that were reported differed in length and amount of detail which may make some easier to remember. Moreover, six experiments across three studies (i.e., experiments 1 and 2 in Barclay and Lalumière 2006; experiments 1, 2, and 3 in Mehl and Buchner 2008; and experiment 4 in Buchner et al. 2009) have failed to replicate Mealey et al.'s results regarding status, despite also investigating the impact of potentially confounding variables such as sex of participant, sex of the face used in the stimuli, attractiveness and likability of the faces used, and time interval between initial display of the stimuli and memory testing (experiment 3 in Mehl and Buchner 2008 did find better memory for faces associated with high-status professions but there was no interaction with cheating or trustworthy behavior). The data from each of these suggest, in contrast to Mealey and Cummins results, that status does not impact detection or memory of cheaters, and thus, that low-status individuals are just as likely to detect and remember high-status cheaters.

Complexities in Cheater Detection, Defining Status, and Enforcing Rules

Current data are equivocal as to whether social status has a meaningful impact on cheater detection in humans. In contrast, a wealth of data suggest that there are other individual and situational variables that may impact cheater detection. For example, Chiappe et al. (2004) found that participants saw it as subjectively more important to remember cheaters compared to cooperators, that this effect was greater when larger amounts of resources were involved, and that subjects were more likely to remember cheaters. In turn, Barclay (2008) demonstrated that the rarity of behavior may play a crucial role in detection and memory by showing that people tend to remember whatever behavior is rarest, regardless of whether that

behavior is cheating or cooperating. In this context, it is important to note that to-date, studies specifically looking at the impact of social status on cheater detection have manipulated relative status via descriptions of occupation or income. In contrast to this, literature and research on social status in humans indicates that social hierarchy is determined by a variety of connected, yet independent, constructs, such as power, socioeconomic status, dominance, prestige, influence, and leadership (Blader and Chen 2014). Furthermore, while social status is often seen as a dispositional characteristic, it is also highly situational, such that someone may be of high status in one environment (e.g., friend group or family) but low status in another (e.g., occupation). In this regard, the constructs used to measure status so far have been relatively narrow and are unable to speak to the broad definition of status in humans.

Moreover, there is typically an important caveat to the idea that low-status individuals should be less likely to notice, remember, and penalize social rule violations by individuals of relatively higher status. Specifically, this should occur to the extent that there is no advantage to detecting cheaters of higher status (Cummins 1999). This situation is believed to appear when lower-status individuals are unable to force high-status individuals to follow social rules. In many nonhuman animals, this appears to be the case. There are reasons to believe, however, that in humans this represents only a subset of possible situations. Specifically, in humans, there are many mechanisms that can be used to enforce social rules, regardless of status. For example, contracts, laws, and courts provide sanctioned and thus official methods of enforcing social rules. Outside of official channels, gossip, exclusion, and public media (e.g., news, social media) provide broader avenues for compelling or penalizing individuals or groups. Of course, an argument can be made that these mechanisms may be more accessible or effective for individuals of higher status. At the same time, it is clear from grassroots campaigns and social movements that lower-status individuals, broadly defined, can also leverage these mechanisms to coerce and punish those of higher

status. Regardless of these specifics, research in humans is currently unable to fully explicate the role of status-based rule enforcement in the relationship between social status and cheater detection.

Conclusion

Evidence to-date is equivocal as to whether lower-status individuals are less likely to detect, remember, and penalize rule violations from higher-status individuals. However, there is a wealth of evidence to suggest that cheater detection is moderated by a host of individual and situational variables. In this respect, investigations into the impact of status have relied on relatively narrow conceptualizations of human status and have not explicitly explored the role of status-based rule enforcement. Future research can clarify the influence of status on cheater detection through boarder investigation into the numerous ways social status is determined in human hierarchies and by considering the role status plays in enforcing social rules.

Rushton, J. Philippe

Edward Dutton

Ulster Institute for Social Research, London, UK

John Philippe Rushton (known as “Phil”) was born on 3rd December 1943 in Bournemouth, a coastal resort in southwest England. He was the eldest of two sons of a Methodist couple: decorating contractor John Rushton (1911–1997) and Andrea Adou alias Adamson (1916–1991). Rushton’s mother was the daughter of a British conscript stationed in France during World War I, John Adamson, and his girlfriend, a French farmer’s daughter, Marguerite Adou; hence

Rushton's Gallic middle name. In 1919, the Anglo-French couple moved to the industrial town of Bolton, near Manchester, where they married (Dutton 2018, p. 121).

In 1948, Rushton's family migrated to Durban in South Africa where Rushton began school. However, they returned to Poole, near Bournemouth, in 1952. Passing an IQ test called the "11-Plus," Rushton attended grammar school (academically focused high school) in Bournemouth. However, in 1956 the family emigrated to Toronto, because Phil's father had got a job as a set artist for the Canadian Broadcasting Company. Aged 15, Rushton became fascinated by both psychology – voraciously reading the works of Hans Eysenck – and politics. He joined the small, libertarian Social Credit Party and sent off for pamphlets published by the International Association for the Advancement of Ethnology and Eugenics (Dutton 2018, p. 121).

Aged 17, Rushton fell in love with his friend's sister, Nina Sack. Dropping out of high school, he took a bookkeeping job for the Canadian railway. Sack became pregnant, the couple married, and in November 1962 they had a son, Stephen Rushton. The couple split up, eventually divorcing, and Rushton became a single father. He began a relationship with Margaret Von Klein (c.1943–2011) and the couple moved to England with dreams of becoming writers, taking Rushton's son with them. Settling in Streatham, in South London, Rushton took a job as a bus conductor. In 1965, Rushton and Von Klein moved to Hackney in the "East End" where their daughter Katherine Marguerite was born in the same year. With two children, Rushton decided he needed a more lucrative job. He did his A-Levels (English school leaving certificate) via a correspondence course. However, during this period Rushton and Margaret split up and Margaret returned to Canada with Katherine from whom Rushton became estranged.

Having completed his A-Levels, in 1967 Rushton began a Psychology degree at Birkbeck College, London, living mainly off the means tested grant that was available to all students at the time, there being no tuition fees. Rushton

graduated with a first class degree in 1970 and transferred to the London School of Economics to pursue a doctorate on altruism in children. In 1973, Hans Eysenck (1916–1997) came to speak at the London School of Economics and Rushton attended. Due to Eysenck's 1971 book on race differences in intelligence, *Race, Intelligence and Education* (Eysenck 1971), this meeting was interrupted by protesters wielding such placards as "No Free Speech For Fascists." Just as Eysenck began to speak, protestors pulled away his microphone, the podium collapsed, and fighting broke out. Believing Eysenck was under a pile of these violent demonstrators; Rushton intervened and was punched in the face (Nyborg 2013).

Rushton spent 1974 as a postdoc at Oxford University before returning to Canada to begin a career as an academic psychologist first at York University and then at the University of Toronto before settling at the University of Western Ontario in London, Ontario, in 1977. He became a tenured professor in 1985. In 1983, Rushton took a sabbatical year working under Hans Eysenck at the University of London's Institute for Psychiatry. As a consequence, he started to become fascinated by race differences and to develop his "Differential K" theory (Dutton 2018, p. 131). According to this model, due to differences in the stability and harshness of their ancestral ecologies, the three main races – Sub-Saharan African, Caucasian, and East Asian – consistently differ in life history speed, with Sub-Saharan Africans the fastest (the most r-strategist); East Asians the slowest (the most K-strategist); and Caucasians intermediate, though closer to East Asians. Rushton presented a large number of measures on which this was the case including twinning, gestation length, age at menarche, intelligence, personality, relationship stability, sexual promiscuity, and longevity (Rushton 1995). In 1988, he first published on this subject and also took up a year-long fellowship with the Guggenheim Foundation. Around this time, Rushton married his second wife, Serpil Kocabayik, a Turkish researcher who completed her PhD in Mathematics at Western Ontario in 1987 (Dutton 2018, p. 138).

In January 1989, Rushton presented *Differential K* at a San Francisco conference at which media were in attendance. This resulted in a media storm, newspaper cartoons of Rushton in Ku Klux Klan robes (over which he sued), Ontario's premier calling for Rushton to be fired because his views were "morally offensive to the way Ontario thinks," left-wing campaigners invading Rushton's department and scrawling "Racists [*sic.*] pig lives here" on his office door, a panicked Rushton being hospitalized with a suspected heart attack, a police investigation into whether he could be prosecuted for inciting racial hatred, his department head grading his research "unsatisfactory" due to its "insensitivity" (against which he successfully appealed), and the Attorney General of Ontario ultimately declaring that Rushton was "loony but not criminal." Until 1991, Rushton's lectures had to be given via video link to avoid student riots, and when he returned to lecturing in person he required security to protect him from protestors (Dutton 2018, pp. 133–134). *Differential K* was divisive in psychology with some condemning it as "racist," immoral, cherry-picked, and based on poor data and others regarding it as a work of near genius (Dutton 2018, Chap. 1). Rushton went on various talk shows to defend his theory and became famous within Canada. While researching *Differential K*, Rushton also accrued data for his "Genetic Similarity Theory": that people tend to be attracted to those who are more genetically similar to themselves, as seen in marital partners and even friends being more genetically similar than two random coethnics, thus allowing people to maximize their genetic fitness via indirect means (see Rushton 2005).

Differential K had been criticized for data it drew upon to supposedly prove race differences in penis size. So, in 1994, Rushton went to the Eaton Mall in Toronto to collect data on this and related matters from males of different races. He paid his subjects with money from the Pioneer Fund, which has been criticized for its alleged association with white supremacism and eugenics, and of which Rushton became president in 2002. In 1995, Rushton published, with a US publisher, his book on *Differential K – Race, Evolution and*

Behavior: A Life History Perspective. Copies were held by Canadian customs officers for 6 months as they investigated whether the book broke Canada's race hate laws.

In 1999, Rushton sent out 40,000 copies of an abridged version of the *Race, Evolution and Behavior* to academics. This led to a furor about its contents with some scholars insisting on returning it to the publisher and the publisher, Transaction, withdrawing the book and the book-proper's second edition, which was published in 2000 (Dutton 2018, p. 137). In the year 2000, Rushton divorced his second wife and married American physical anthropology researcher Elizabeth Weiss (b. 1973), also producing a third edition of *Race, Evolution and Behavior*, which he published via his Charles Darwin Institute (Dutton 2018, pp. 127–138).

Around 2001, Rushton's estranged daughter, who had been raised in care, got in touch with him and in 2003 his third marriage broke down. In the same year, Rushton was diagnosed with the rare condition Addison's disease (Dutton 2018, pp. 140–141). He also became particularly interested in a "General Factor of Personality" (GFP); the idea that the Big 5 personality traits can be reduced to one essential factor of social effectiveness (see Nyborg 2015).

In 2005, Rushton became involved in another controversy when he told *The Ottawa Citizen* that black immigration into the city would precipitate its decline and lead to the death of "Toronto the Good" due to supposed low black IQ. By this time, Rushton was regularly speaking at far right-wing conferences, such as those run by *American Renaissance*, and writing for related magazines, such as *V-Dare* and *Right Now!*. In 2008, Rushton was door-stepped by a TV reporter asking, "Are you a racist?" Clearly irked, Rushton made his way to his car and lifted his wheeled suitcase in such a way that the reporter's microphone hit the reporter in the face, cracking the reporter's tooth (Dutton 2018, p. 142). Between 2010 and 2012, Rushton transferred half of the Pioneer Fund's money to his Charles Darwin Institute. He then bequeathed this to his son who changed its name to JSP and used it to establish a scholarship fund at the university where he

works in Florida. Accordingly, half the Pioneer Fund could no longer be used for the kind of research – on such areas as race – for which the fund was established (Dutton 2018, pp. 143–144).

Rushton, by that time a great grandfather, died of cancer in the palliative ward of Victoria Hospital in London, Ontario, on 2nd October 2012. An opinion piece, 2 days later in the *London Free Press* (Gilespie 4th October 2012), was headlined “Rushton’s Ideas Died With Him.” By contrast, an obituary in *The Big Think* by psychologist Satoshi Kanazawa (10th October 2012) compared Rushton to Galileo, as the exemplar of the scientist persecuted for telling the truth, stating that “Unlike Galileo, he never recanted.” In 2013, the journal *Personality and Individual Differences* published a special issue on J. Philippe Rushton and his work which was subsequently republished in book form (Nyborg 2015).

Sacred Values

Definition

Those values that a moral community treats as possessing transcendental significance that precludes comparisons, trade-offs, or any mingling with secular values.

Introduction

The use of sacred values by humans to enforce cooperation has been seen throughout human history, as demonstrated by philosophers like Marx and Aristotle observing that humans are more likely to follow rules when framed from a sacred view of “don’t do x because God says so” versus a secular view of “don’t do x because I say so” (Tetlock 2003). As these types of rules are common across all cultures, anthropologists began noticing that, although the value being upheld was vastly different between cultures, the presence of sacredness was near ubiquitous. This led to research into the psychology of sacred values.

Sacred Values

Sacred values are those values which humans attribute a priceless value to. This means that, regardless of what the costs of upholding the value are, these costs will not typically outweigh the costs of giving up the value. However, because there is only a limited amount of resources available to us, humans will give up their sacred values if the cost to maintain them is too high. This belief that a sacred value is priceless, yet a willingness to give it up given the right circumstance, has led psychologists and political scientists to study sacred values further (Tetlock et al. 2000).

The major area of research on sacred values has focused on its application to international conflicts (e.g., Atran and Axelrod 2008). Given that many of these conflicts are caused by perceived transgressions, understanding the mechanisms behind these values is important. To understand how these values operate, Atran and Axelrod (2008) argue that sacred values may not be cultural, but evolutionary. Sacred values likely evolved to counter evolutionarily recurrent problems that posed long-term threats to our ancestors. One example is the presence of children. Indeed, a consistent sacred value across cultures is the importance of children to parents. For the parents, their children’s safety is frequently presented as a priceless condition, not to be compromised even if offered large amounts of resources (e.g., time, money, health) or great sacrifice (e.g., giving up one’s career or even life).

Conclusion

Sacred values are a ubiquitous part of everyday life, and although the specific content of a value may shift across cultures, the presence of values with sacred beliefs attached is cross-culturally consistent. As these types of values can be charged with violence when transgressed, they are frequently the cause of many international conflicts (e.g., religious wars). Because of this, much research has been devoted to understanding their presence from an evolutionary perspective to better negotiate peaceful resolutions.

Definition

Disgust is a sociomoral emotion elicited by moral violations against sacredness and purity of body and spirituality.

Disgust is one of the fundamental and universal human emotions like fear, anger, sadness, and joy (Ekman et al. 1969). In broader terms, disgust is a defense mechanism against purity and sacredness of body and soul. Common behavioral responses of disgust are gape face, feeling of nausea, physical avoidance from the disgusting stimulus, and the stimuli contaminated by the source stimulus. In addition to behavioral responses, common cognitive responses are a sense of being offended and contaminated. Two kinds of disgust have been defined in the literature: a nonmoral form of disgust defined as visceral disgust, which guards the body against threats to its integrity, and sociomoral disgust as a reaction to moral transgressions of others (Rozin et al. 1993).

Core disgust is thought to be an evolutionary adaptation to protect the gastrointestinal system (Schaller and Park 2011). Accordingly, disgust sensitivity generally operating as an orally based aversion prevents digestion of toxic and poisonous food. Behavioral responses like nausea also help us avoid harmful foods via preventing immediate digestion. Another function of core disgust as an evolved mechanism is to protect the body against pathogens. Accordingly, disgust leads to avoid physical contact with infected and contagious stimuli as well as avoiding places where pathogens can be carried (Rozin et al. 2008). Reflex-like withdrawal behaviors and purity concerns are also other behavioral mechanisms protecting the organism.

Aside from being a response to harmful foods and pathogens, disgust is a response to a number of moral violations as hypocrisy, betrayal, and cruelty (Miller 1997). A theoretical framework to understand disgust as a sociomoral emotion is provided by contempt, anger, disgust (CAD) triad hypothesis (Rozin et al. 1999) which is then incorporated to the Moral Foundations Theory (MFT; Haidt 2007). This line of research highlights the importance of emotions and unintentional gut reactions in terms

of moral judgement unlike the cognitive developmental tradition (e.g., Piaget 1932/1965; Kohlberg 1969) which focuses on rational thought processes to explain the cognitive roots of morality. According to this view, there are several moral emotion clusters such as “self-conscious” emotions including shame, embarrassment, and guilt, whereas disgust is one of the “other-critical” moral emotions along with contempt and anger. Those “other-critical” emotions are triggered by specific ethical violations. Those violations are, that derived from the work of Shweder et al. (1997) work on Hindu Indians, autonomy (individual freedom and rights), community (social hierarchy), and divinity (sacredness and purity regarding God, oneself, and others). Ethical violations to one of those concerns elicit anger, contempt, and disgust, respectively. The link between disgust and divinity further explained by MFT which proposes evolutionary rooted five universal moral foundations. Those foundations are care/harm, fairness/cheating, loyalty/betrayal, authority/subversion, and sanctity/degradation foundations. Accordingly, human beings use those five moral intuitions, which are emotion-based and partially unconscious, to make moral judgments. Sanctity/degradation is associated with controlling bodily desires and protecting and preserving sacredness and purity of body and soul. Since sanctity foundation is assumed to be unique to human considering the exclusiveness of disgust and fear of contamination among species (Rozin and Fallon 1987), it is assumed that sanctity evolved most recently among other moral foundations in line with religious beliefs commonly seen in human societies.

As a result of this evolutionary process, it is thought that behavioral immune system to protect organism is generalized to moral issues which are not directly linked to survival instincts manifested by disgust sensitivity (Schaller and Park 2011). Accordingly, during the evolution of the moral domain which defines oughts and things to be avoided, at some point it is converged with the evolution of disgust as an immune system. Therefore, disgust became a response mechanism for social and abstract issues as religious views and political ideologies. In other words, disgust

became a way to differentiate what is pure and sacred against impure and immoral at the individual level. For instance, it was found that higher levels of disgust sensitivity are related to higher levels of motivation to maintain physical and spiritual purity (Horberg et al. 2009). Likewise, reminders of physical purity increased political conservatism and condemnation of incest and masturbation (Helzer and Pizarro 2011). Further, disgust helps to foster cooperation and group cohesion by creating powerful negative emotions against out-group members. For instance, triggering disgust with noxious odor is related to negative attitudes towards gay people (Inbar et al. 2011). Similarly, reminders of the contagious disease led to an increase in negative attitudes toward immigrant people (Faulkner et al. 2004).

Disgust is an emotional reaction to protect organism against harmful food and pathogens, and it is also an emotional reaction to protect and preserve sacredness and purity against threats to moral values. This sociomoral function of disgust plays role in forming social attitudes and relevant behaviors.

Definition

A person's social category is salient when he or she is perceived, or perceives himself or herself, as a group member rather than as a unique individual. Category salience implies that the impression of and the behavior towards the person shift from the interpersonal level to the intergroup level.

Introduction

Psychological theory and research has extensively focused on the process of social categorization, its antecedents, and consequences. A person's social category is salient when he or she is perceived, or perceives himself or herself, as a group member (e.g., a “woman” or a “manager”) rather than as a unique individual. Category salience implies that the impression of and the behavior towards the person shift from the interpersonal level to the intergroup level. Without category salience, intergroup behavior is not possible – behavior between groups can only be shown if people categorize each other into groups. Therefore, social category salience is the most fundamental

foundation of stereotyping, social identity formation, and intergroup relations. According to self-categorization theory (Turner et al. 1987), category salience is determined by the interaction between the relative accessibility of the category for the perceiver and the fit between stimulus input and stored category specifications. Accessibility means how readily a given category becomes cognitively activated and it reflects the goals, motives, and circumstances of the perceiver. In contrast, fit refers to the extent to which a distinction between social categories matches reality in both its comparative and normative aspects (Bruner 1957; Oakes 1987). In situations in which people's social categorizations of themselves and others become salient, they are more likely to define themselves and others as group members and thus to engage in stereotyping, intergroup behavior, and conflict. Intergroup bias in return is likely to affect team performance in work settings.

Salience of Social Categories and Stereotyping

Research has consistently demonstrated that variations in the salience of social categories influence self-perception, impressions of others, attitudes, and behavior (Fiske and Neuberg 1990; Oakes 1987). Stereotypes are cognitive representations of prominent attributes of group members, which result from the cognitive process of categorizing social groups. While categorizing others might be beneficial for the person who engages in the process (e.g., it reduces the complexity of our world; Macrae et al. 1994), perceiving and treating others as group members, rather than unique individuals, can foster stereotyping and prejudice, which in turn may create discrimination.

Social categories such as a person's sex, ethnicity, or age are particularly likely to affect perceptions and judgments of others as they are readily visible and immediately evident. In contrast, categories such as a person's personality or values are less likely to impact immediate impression formation and judgments of others, as they are not so immediately apparent to people.

Research has further shown that any social category can become salient as a function of the social environment in which the individual is perceived. For example, in an experiment in which the salience of gender in the classroom was manipulated, via frequent exposure of children to gender classifications (e.g., lining up children by sex or not), teachers in the high gender salience classroom produced stronger gender stereotypes among their pupils and less positive attitudes toward peers of the other sex and less willingness to play with them (Hilliard and Liben 2010). Similarly, Retelsdorf et al. (2015) found, in a time-lagged study, that teachers' beliefs about reading favoring girls at time 1 were negatively associated with boys' (but not girls') reading self-concept at time 2. Exploring the role of salience in age stereotyping in simulated employment settings, one meta-analysis found that younger workers have higher mean job qualification ratings than older workers when age is salient (Finkelstein et al. 1995), i.e., when raters judged old and young workers concurrently, than when age was not salient, i.e., in a between-subjects condition design. Additionally, when individuals are distinctive, unique, or "token" members of their social categories, that category becomes contextually more salient and guides observers' impression of these individuals or the individual's own perception and judgment. Indeed, numerically rare group members are perceived more stereotypically (Kanter 1977; Oakes et al. 1991; Taylor et al. 1978). In particular, several studies have documented how rarity of women negatively impacts others' perceptions of and behavior toward women in work settings (e.g., Heilman 1980; Sackett et al. 1991; Taylor et al. 1978). For example, in her hiring study with MBA students, Heilman (1980) varied the sex composition of the applicant pool and found that raters evaluated female applicants as less favorable and as more stereotypical when the applicant pool included only 25% women or less. These rarity effects bear even more important implications as women rise in organizational hierarchies. Women will be increasingly in a minority position and their female-stereotypical qualities will become more salient, which – due to their incongruity

with stereotypical male qualities perceived in leaders – might produce disadvantages for women (see Eagly and Karau 2002). In general, in organizational settings compared to other settings, people's behavior is less stereotypic because organizational roles (e.g., based on occupation or status in the organizational hierarchy) tend to be more salient and therefore more impactful than diffuse roles (e.g., based on gender, age, or ethnicity), consistent with social role theory (Eagly et al. 2000). Demonstrating the powerful impact of *social roles*, experiments showed that gender-stereotypical trait judgments were reduced, or even eliminated, when men and women were portrayed as occupying the same role (e.g., nurse, firefighter) than without role information (Bosak et al. 2008, 2012).

Social category salience however does not only impact others but also individuals' self-perception and behavior. People learn the content of stereotypes (e.g., gender stereotypes) and can internalize stereotypes into their *self-concept*. Thus, if a stereotype is cognitively activated following a process of social categorization, *self-stereotyping* can occur and have individuals act in a way consistent with their stereotype. One area in which the powerful effect of self-stereotyping can be observed is career aspirations and choices. Bosak and Sczesny (2008), for example, found that women, compared to men, judged themselves as less suitable for an advertised leadership position because they perceived themselves as possessing fewer of the agentic traits (e.g., assertive, competitive) typically ascribed to leaders and men. Another area in which self-stereotyping and its negative impact on the behavior of group members can be observed is stereotype threat (see Hoyt and Murphy 2016). Demonstrating the powerful influence of social-cultural stereotypes on individual performance, Shih et al. (1999) made one of two social-cultural identities to which participants belonged salient. Specifically, these researchers found that Asian women, whose gender identity was made salient, underperformed in a math test, whereas those who were subtly reminded of their Asian identity performed better than participants in the control condition. Thus, the salient identity can hinder or facilitate performance. This

finding applies even to members of traditionally advantaged groups in certain situations. For example, in another stereotype threat experiment, White men underperformed on a math test when beliefs about Asian superiority were made salient (Aronson et al. 1998). Finally, salient role models have been found to buffer the negative effect of stereotype threat on performance (see, for example, the “Obama effect” for African-Americans; Marx et al. 2009).

A powerful demonstration that socio-cultural stereotypes ascribed to salient categories fulfil a function is given by the stereotype content model (SCM; Fiske et al. 2002). Stereotypes in terms of warmth (“Are they friend or foe?”) and competence (“Are they capable of reaching their goals?”) provide fast and the most fundamental information about outgroups. Stereotypes based on these fundamental dimensions (e.g., physically disabled people as warm and incompetent; business women as cold and competent) have been shown to appear across cultures (e.g., Asbrock 2010; Cuddy et al. 2009) and to predict specific emotional and behavioral reactions toward the respective outgroups (e.g., Becker and Asbrock 2012; Cuddy et al. 2007).

Salience of Social Categories and Intergroup Behavior

A social identity refers to membership of a social group and a certain emotional value attached to this group (Tajfel and Turner 1979). According to the social identity approach (Tajfel and Turner 1979; Turner et al. 1987; see Abrams and Hogg 2010, for a review), social identities rely on the conceptualization of *social categories as groups*, that is, on the salience of a social category and one's awareness of being connected with this category. The sufficiency of these two factors for intergroup behavior has been shown in research applying the *minimal group paradigm* (MGP; Tajfel et al. 1971). Individuals are assigned to one of two groups based on a random or trivial criterion. Subsequently, the individuals allocate money or tokens to others, only knowing the other person's group membership and a code

number. Hundreds of MGP experiments have shown that minimal group information was sufficient to elicit a preference for the ingroup (ingroup bias) in the distribution (Diehl 1990).

Social identity is an important part of the *self*, and individuals strive for enhancing or maintaining a positive social identity by positively distinguishing their ingroup from relevant outgroups. According to social identity theory (SIT, Tajfel and Turner 1979), group members can adopt several strategies for this purpose, depending on the permeability, legitimacy, and stability of the respective group boundaries. While permeable group boundaries allow for leaving a low-status group and moving into a group with higher status, low permeability calls for social creativity or social competition measures. Social creativity allows for regaining a positive social identity when group boundaries are perceived as stable and legitimate, for example, by downward comparison with a lower status group instead of unfavorable upward comparison with a higher status group (e.g., Blanton et al. 2001). Other social creativity strategies are a positive reevaluation of the value of the comparison dimension (e.g., “black is beautiful”) or a comparison with the outgroup on an alternative, more ingroup-beneficial dimension (but see Martiny and Rubin 2016, for a critical review).

If group boundaries are perceived as illegitimate, group members adopt social competition strategies and directly confront the status relations in order to change them or to maintain the social hierarchy. Low-status groups can engage in collective action to improve their status (Van Zomeren et al. 2008), and high-status groups can discriminate against outgroup members to maintain their status (Sachdev and Bourhis 1991). However, different strategies to regain positive social identity can interfere with each other. In a series of experimental studies, Becker (2012) tested if engaging in social creativity, (e.g., gaining a positive social identity by comparing one’s group with a lower status group), enhanced social identity for low-status groups but simultaneously undermined collective action intentions. As predicted, participants from different samples

(women, students, and unemployed people) showed fewer intentions to engage in collective action and change the status quo of the ingroup after engaging in social creativity strategies.

Individuals possess many group identities (Tajfel and Turner 1979) and these identities can change with goals, motives, experiences, or perceptions. According to the common ingroup identity model (Gaertner and Dovidio 2000), recategorization of in- and outgroup members elicits changes in ingroup bias. Recategorization of outgroup members into a common superordinate ingroup makes them members of the ingroup and, therefore, provides them with those positive emotions, beliefs, and behaviors directed towards ingroup members. Recategorization does not necessarily lead to the abandonment of the less inclusive ingroup identity. Group members can develop dual identities, and superordinate identities can include subgroups. Gonzáles and Brown (2003, 2006) showed that dual identities are effective in facilitating intergroup contact effects relative to a one-group representation. Recently, Hehmann et al. (2012) provided evidence that group status moderates the preference for single or dual identities of common ingroups. Both, minority and majority group members strive for a common ingroup identity that is most beneficial for their group. For majority groups, this is a one-group representation, as it draws attention from disparities between the subgroups and therefore reduces subgroup identification and collective action in the minority subgroup. Minorities, however, prefer dual identities, because subgroup identification increases the likelihood of detecting injustice between the subgroups and confronting it via collective action (Gaertner et al. 2016). Ufkes et al. (2016) recently confirmed the advantage of a dual identity over a single-group identity for minority group members. They showed that increasing the salience of a common US identity for categorizing Blacks and Latinos in the USA undermined their collective action intentions, while salient dual identities did not. Simon and Ruhs (2008) found evidence that Turkish migrants in Germany holding a dual identity as Turks and Germans engaged in normative but not nonnormative political behavior.

Despite these benefits, dual identities can harm intergroup relations. Subgroups can perceive their ingroup as more prototypical for the superordinate group (e.g., people from West Germany might perceive themselves as more prototypical of Germans than people from East Germany) and perceive the outgroup as substandard or inferior, leading to more bias (Mummendey and Wenzel 1999; Wenzel et al. 2008). Whether dual identity increases or decreases intergroup conflict depends on perceived prototypicality, relevance, and diversity of the superordinate category, as well as on the outgroup status (Hall and Crisp 2005; Steffens et al. 2017; Verkuyten and Martinovic 2016).

Salience of Social Categories, Diversity, and Team Performance

The salience of social categories plays an important role in many applied contexts. One prominent application of research on social category salience is organizational research on the effects of (team) *diversity*. This research employs social categorization approaches (see Meyer 2017; Williams and O'Reilly 1998, for reviews) to propose negative effects of team diversity. (To be clear, this research also proposes a competing positive effect of team diversity on team performance.: Information processing advantages of heterogeneous groups are likely to increase creativity and problem-solving performance of diverse groups (e.g., Williams and O'Reilly 1998; van Knippenberg and Schippers 2007).) If team members perceive each other as belonging to different social categories on the basis of salient social categories, *intergroup bias* ensues among employees who are supposed to collaborate towards a common goal, with detrimental consequences for inter-category communication and trust (van Knippenberg et al. 2004; van Knippenberg and Schippers 2007). Consequently, if colleagues construe their interpersonal demographic differences in terms of different social categories that signal identities, negative consequences are likely to ensue (Shemla et al. 2016; Carton and Cummings 2012).

However, empiric evidence for these arguments is mixed. Several meta analyses on the

effects of team diversity (Bell et al. 2011; Horwitz and Horwitz 2007; van Dijk et al. 2012) did not identify a consistent negative main effect of team diversity on team processes and performance. This indicates that interpersonal differences are not automatically associated with social categorization processes and intergroup bias on the basis of salient social attributes. Indeed, the effects of team diversity appear to be largely context-dependent (Joshi and Roh 2009). However, the negative consequences of demographic differences among members of a social unit are more likely to materialize if multiple differences with regard to several potential social categories are aligned in the same way. *Faultlines*, hypothetical dividing lines splitting a group into relatively homogeneous subgroups on the basis of several attributes (Lau and Murnighan 1998), are associated with more conflict and decreased performance in teams, as a meta-analysis indicates (Thatcher and Patel 2012). This is likely to be the case because faultline strength – which researchers can quantify with different algorithms (Meyer et al. 2014) – constitutes an applied operationalization of the meta-contrast from self-categorization theory (Meyer et al. 2011; Meyer 2017). Self-categorization theory (Turner et al. 1987) posits that social categories become salient on the basis of stimuli, which are grouped together into a category in such a way that within-category homogeneity of stimuli is maximized and between-category heterogeneity of stimuli is maximized. This ratio of within-and-between category heterogeneity, i.e., the average difference between categories divided by the average differences within a category, is the meta-contrast (Turner et al. 1987). Faultline researchers typically operationalize faultlines in the same way. The two most frequent measures of faultline strength, Thatcher's Fau (Thatcher et al. 2003) and Average Silhouette Width (ASW, Meyer and Glenz 2013), deliver the ratio of within-subgroup heterogeneity of several demographic attributes to between-subgroup heterogeneity of these attributes, where larger values indicate that the differences lie between subgroups, not within subgroups. In sum, applied organizational measures of faultline strength offer a quantification of

the meta-contrast of self-categorization theory. Perceiving the faultline – in other words, if the categories that are distinguished by the faultlines become salient – results in comparative fit, “the extent to which observed similarities and differences between people or their actions are perceived as correlated with a division into social categories (Turner et al. 1987)” (Meyer et al. 2011, p. 261). Accordingly, if team members subjectively perceive a faultline within their social unit, i.e., if faultlines become active in contrast to being dormant (cf. Jehn and Bezrukova 2010), the negative effects of faultlines intensify (Thatcher and Patel 2012). Thus, in sum, the findings from applied research on team diversity and faultlines is very much in line with the predictions of the self-categorization theory with regard to the salience of social categories.

However, some findings of this line of research also extend classic theories and knowledge surrounding category salience. Research on team and societal diversity (Kauff and Wagner 2012; Kauff et al. 2013) indicates that perceived interindividual differences on the basis of salient social categories do not entail outgroup devaluation if perceivers see value in diversity. The same is true for faultlines – teams consisting of members who see value in interpersonal differences are not negatively affected by team faultlines (Homan et al. 2007).

Conclusion

Social category salience is fundamental to intergroup perception and behavior. Category salience is a function of the Fit $\times$ Accessibility interaction. In situations in which individuals perceive themselves and others as belonging to different social categories based on salient features, they tend to engage in (self-) stereotyping and intergroup bias. While stereotyping and intergroup bias can yield detrimental consequences for individual group members as well as teams (e.g., discrimination, intergroup conflict, lower team performance), salient positive identities and dual identities can also bring positive consequences and advantages with them (e.g.,

invulnerability to stereotype threat, absence of harmful collective action).

Definition

Individuals who have lower status in the dominance hierarchy use elements of a behavior repertoire which help reduce the aggression of dominant group members.

Introduction

Throughout our lives, we are part of many different groups: school, sport club, book club, pet lovers' club, knitting club, and so on and so forth. In all these different groups, we all have our own role and position which might very well be different in each of them. And that is because humans, just like other animals, form hierarchies. Depending on the social context, people may have different ranks in different groups. In some cases, rank is achieved via aggression – the dominant individual defeating the subordinates. Leadership characteristics can also lift someone to dominant status.

The advantages of being dominant seem rather obvious: better access to resources and possible mates. At the same time, however, protecting

members of the group might expose them to danger. On the other hand, a subordinate enjoys certain advantages as well, mainly those coming from being a member in the group: safety, knowledge and information, and not having to solve in-group conflicts. This natural order is advantageous to all parties and is a means for minimizing aggression within the group (Eibl-Eibesfeldt 1989).

Tactics to Rise in the Hierarchy

Aggression, as it is, is more of a characteristic of male dominance negotiation: open fights for the top rank (Buss and Shackelford 1997). This, of course, would put a continuous strain on the opponents and the chance of suffering major injuries. For this reason, humans and animals alike use expressive movements such as facial expressions and other ritualized attack movements. One very common example of ritualized fighting is verbal conflict (Eibl-Eibesfeldt 1989). This, as opposed to physical aggression, shows no sex difference: females use verbal aggression just as much as men do. The difference between the two sexes regarding the type of aggression they are likely to use is in part the consequence of sex-specific intra-sexual strategies (Buss and Shackelford 1997), just as it is the consequence of childhood experiences (Lauer 1992).

Tactics of Subordinates

So far, research has accumulated many pieces of information on what negotiating dominance is like, but we do not know quite as much about the other side, namely, the tactics subordinates use. From animal studies it has been gathered that strategies of submission, such as nod of the head, making oneself seem “smaller,” prostrating oneself, and adopting a childlike manner, help block aggression of dominant individuals (Eibl-Eibesfeldt 1989). Smiles, humor, self-deprecation, and breaking eye contact are also appeasements that are meant to reduce others' agonistic motivations. It has also been observed that between sexes, flirtation is an affiliative tactic (Salter et al. 2005). For example, young women use physical attractiveness as a tactic to persuade opposite-sex strangers to do favors (Davies

et al. 2008). Sexual stimuli have been said to lower aggression in males (Salter et al. 2005).

Sex Differences in Subordinate Tactics

In their study, Salter et al. (2005) observed whether courtship signals serve as appeasement techniques when facing aggressive authority. For this purpose they observed the behavior of would-be patrons (i.e., people who wanted to enter) and doormen outside of a German nightclub.

The researchers analyzed video footages of patrons approaching a nightclub in Munich and their interactions with doormen. From the videos various behavioral categories were constructed. Doorman threat behavior included watching patron, turning and moving toward them. Greeting doormen, nodding, smiling, talking to doormen, touching their face or hair, putting their hands in pocket, parading, and swaying were considered patron behavior categories. Patrons' appearance was also rated, namely, their "sexiness": the tightness of clothing and the proportion of skin showing over the legs, torso, and arms.

There was a significant difference in attention and threat male and female patrons received from doormen when there was only one doorman. The average duration of threat from a single doorman was higher for men than it was for women. This difference, however, was not significant when there was more than one doorman.

As hypothesized by the authors, the behavioral repertoire used by the two sexes differed significantly. They also differed in approach speed, showing that men accelerated while women slowed down when there were three or more doormen present. The authors interpreted this strategy as "fleeing through the threat" when males try to minimize exposure in face of threat. This strategy also included minimizing anxiety by masking agonistic affects. On the other hand, women slowed down, the authors reason, to give themselves time to execute an appeasement strategy that involved mannerisms (i.e., behaviors performed predominantly by one sex) like parading, stroking their hair, smiling, and touching their face. Moreover, females' clothing style and their behavior showed a correlation which supports the notion that women's mannerisms are qualitatively

different from those of men. Women who were wearing clothes that were tight and left their legs bare also tended to show more mannerisms. The authors interpret clothing style as an interpersonal tool in appeasing male aggression and at the same time attracting mates, by releasing sexual motivation in them. An alternative to this is that stereotypical female dress and gestures enhance attractiveness (apart from being a tool for appeasement), which doormen use for judging whether to admit a female into the club or not. Using one's attractiveness has been also said to increase the chances of persuading an opposite-sex person to do a favor (Davies et al. 2008).

Conclusions

Belonging to a group with a stable hierarchy is advantageous for both dominant and subordinate individuals. Depending on the sex of the individual and the actual rank in the hierarchy, the behavioral repertoire used to maintain the status, and to avoid unnecessary collisions, may vary. Salter et al. (2005) presented data from real-life observations illustrating this assumption. Females seem to use sexually releasing behaviors to lower male aggression, whereas males try to mask their anxiety and minimize exposure time to threatening males.

Same-Different Categorization

Definition

Same-different categorization refers to the ability to judge two or more objects or events as sharing an attribute or as being dissimilar with regard to an attribute.

Introduction

It is unequivocally accepted that humans have the capacity to reason about sameness and difference. It is also apparent that many animals share the capacity to generalize responses between items that are the same or different. Reasoning about sameness and difference at a more abstract level is more difficult to ascertain, however, and is important because it reflects an ability to think about relations between objects, rather than simply representing the perceptually apparent properties of the stimuli – a feat that many animals can easily perform. Scientists have acknowledged the importance of this ability from the dawn of the study of psychology.

Demonstrating Sameness/Difference Concepts in Nonhumans

Being able to detect similarities and differences amongst natural stimuli is critical for survival in any environment as this ability allows an organism to generalize what it has learned to other members of the same categories. For instance, an animal could learn that it is safe to eat fruits and vegetables but that it is not safe to eat other kinds of vegetation, such as poison ivy. The same animal can learn to avoid predators while not being alarmed by other prey species. Animals may make such generalizations by attending to perceptual features and learning to respond in similar ways to stimuli that possess a similar attribute, such as eating a fruit with a faintly sweet odor and bright color. However, to truly represent concepts for sameness and difference, it must be possible to show that animals can respond to items based on the relation of sameness or difference between these items regardless of whether specific attributes are the same or different. For example, an animal might know that the relation between a red grape and a purple grape is the same as the relation between a green pear and a yellow pear – both are sameness relations, but the actual colors differ. To make this assessment, the animal must attend to relational features, rather than absolute perceptual features of the stimuli.

In order to demonstrate same-different categorization at a conceptual level, it might also be useful to show that animals can classify items together based on a nonperceptually evident common feature. For instance, humans can categorize people based on qualities of introversion or extroversion and employment positions and can categorize various disparate objects into functional categories such as “household, decorative, tool, toy, etc.” Little empirical work has been done thus far to investigate these more abstract sameness judgements in nonhumans.

It is relatively easy to assess same-different categorization in most humans because researchers can ask individuals to indicate verbally which items are similar or different, what makes them similar or different, and which items should be classified together. Most animals cannot respond in such tasks, with the possible exception of Alex, the grey parrot, who answered questions such as “What is same” with responses such as “color, shape, and matter” (Pepperberg 1987). Despite this limitation, it is still relatively easy to assess same-different categorization at a purely perceptual level using a variety of paradigms that have been applied to nonverbal infants and extended to nonhumans ranging from honeybees (Giurfa et al. 2001) to chimpanzees (Parr and de Waal 1999).

With infants, researchers use habituation/dishabituation tests in which the infant is shown an image until looking time to the image declines (i.e., habituation). When researchers present a novel image, looking time increases, indicating that the infant recognizes the change in the stimulus. If researchers present the same stimulus after a short interval, infants do not look at it for very long, indicating familiarity, but after longer intervals, looking time increases again. This procedure tells researchers when an infant can perceive a stimulus as the same, even when it is presented at different time intervals. When children are old enough to make operant responses, but too young to verbalize similarities and differences, they may be presented with tasks such as sorting, in which objects of one type (e.g., based on shape, color) are placed in one container, while objects of another type are placed in a different container.

Nonhuman primates can be trained to perform sorting tasks as well. Sorting tasks can also be performed on the computer using the well-known Wisconsin card sorting task. A broader range of species have been trained in match-to-sample tasks where they are shown a sample (either a real object or a two-dimensional depiction) along with two or more comparison stimuli (either simultaneously or successively) and they are tasked with selecting the stimulus that matches the sample. Matches can be perceptually identical to the stimulus (as in identity matching) or share some attributes, such as shape or color (Vonk 2003), or match based on an underlying construct, such as numerosity (Vonk 2014), taxonomic category (Vonk 2013), relatedness (Parr and de Waal 1999), or emotional valence (Parr 2001). The perception of sameness can also be assessed by allowing subjects to indicate particular responses for members of the same category. For example, in many of Wasserman’s classic categorization tasks, pigeons are trained to select one key for flowers and different keys for cars, chairs, and people (e.g., Lazareva et al. 2004). Pigeons are successful at this task, indicating that they perceive the similarity between different members of the same class/category. Most of these tasks are presented on touch-screens where animals can directly contact the correct stimuli or response keys.

A more abstract concept of sameness and difference is tested when animals must respond based on the sameness relation between stimuli that are not themselves identical. That is, they must determine that the relationship between a group of items that are the same is the same relationship depicted by a different group of same items. Whereas many animals, including pigeons and rhesus macaques, can learn to match arrays of stimuli based on whether all of the items in the array are similar or different, their accuracy declines as the number of items in the array declines. Performance when only two items are depicted falls to chance (Wasserman and Young 2010). Orangutans and gorillas, on the other hand, successfully matched items based on shared shape or color when only two items appeared in the arrays (Vonk 2003). Although some researchers

have concluded that the ability to perceive abstract relations is unique to humans (Penn et al. 2008), these results from other great apes suggest that the capacity may be shared at least within the apes. These same apes were also able to match stimuli based on second-order relations (e.g., two items of the same shape were matched to two other items of a different shape when compared to two items of different shapes; Vonk 2003). Although insects, fish, birds, and mammals may share the capacity to match based on sameness, these results may be due to perception of variability or entropy, thus explaining why performance declines with fewer items in the arrays. Thus, although it is clear that many different species wield the capacity to respond to variability, it is not clear whether the underlying mechanisms for such behavior are the same as those that underlie understanding of sameness and difference as abstract concepts, as in humans (e.g., Wasserman and Young 2010).

Conclusion

Although the extent to which nonhumans truly represent sameness and difference at the same level of abstraction as humans do is debatable (Penn et al. 2008), it is clear that they are able to perceive similarities and differences and to use these judgements to inform responses.

Same-Sex Coalitions That Exclude Women

Definition

Males show a preference for forming and maintaining large social groups composed of same-sex peers. This tendency is argued to be a mechanism for forming coalitions to engage in intergroup warfare.

Introduction

From a young age, males show a proclivity for forming large same-sex social groups. This is contrasted by the dyadic relationships generally preferred by females. One explanation for this preference among men to form large groups of same-sex peers is that it is an evolved mechanism for building and maintaining coalitions that function to protect the group from attack by outsiders and that can be used to attack outgroups. This entry will describe the evolutionary evidence for why such a mechanism should be restricted to men rather than women and review evidence from the literature providing support for the idea that these same-sex male coalitions serve the function of facilitating success in intergroup warfare.

Evolutionary Background

Observation and study of human history show that human aggression is typically perpetrated against

and by males (Daly and Wilson 1983). Differences in male and female reproductive physiology incentivize greater competition among males to secure access to mating opportunities. This includes competition among men within a group but also the banding together of men to protect the group and its resources from attack by outsiders, as well as the acquisition of resources from other groups via preemptive attacks.

These ideas are built on the foundation provided by parental investment theory which states that the sex that invests fewer resources into offspring (i.e., males) will compete more aggressively for mating opportunities (Trivers 1972). In other words, given their reduced obligatory investment to offspring, males can optimize reproductive success by increasing the number of females with whom they mate. However, this strategy requires a high level of competition with other males for mating access. In contrast, owing to their reproductive biology, females have a highly constrained reproductive ceiling and therefore benefit most from finding mates who will invest heavily in their offspring. As a result, female preference drives competition among males. A man's failure to compete can lead to the end of his lineage.

Given the male reproductive strategy, gaining access to reproductive resources is incredibly important. These resources can be direct (i.e., mating access to women) or indirect, such as in the form of financial resources or social status that attract women. Thus, engaging in intergroup conflict can be a highly beneficial endeavor as victory allows males of one group to acquire the resources of the defeated group (both direct and indirect). Although there are risks involved in one's participation in intergroup conflict, certain conditions can shift the balance of risk and reward. For example, Tooby and Cosmides (1988) have argued that warfare is most likely to be initiated when the chance of victory is high, when the risk of bodily harm is distributed equally across all members of the coalition, and when it is believed that any resources gained from conflict will be split equally among victors. Consequently, if warfare is only initiated when the

potential risk of a defeat is quite low, then the cost-benefit ratio may often favor warfare among males.

Building on these ideas, the male-warrior hypothesis (Van Vugt 2012) suggests that, owing to the reproductive advantages gained by men who engage in intergroup conflict under favorable conditions, men's psychology will be equipped with psychological mechanisms that function to motivate men to engage in warfare and that increase their probability of success. One such mechanism is the tendency to build large same-sex coalitions of males. Indeed, group size is a key predictor of warfare in tribal societies (Wrangham and Glowacki 2012). Along these lines, tribal warfare produces very few casualties on the side of the attackers, primarily owing to the asymmetric group size and the strategic advantage it affords. If large coalition size can function to deter attack from outsiders and nearly assure victory in asymmetric attacks on an outgroup, then men's preferences to form large coalitions of same-sex males should be quite strong.

Male Coalition Building

From a young age, males report larger peer groups as compared to the peer groups reported by females (Benenson 1990). Males are also significantly less likely than women to ostracize same-sex peers over an internal conflict, choosing instead to "bury the hatchet" (Benenson et al. 2013). This phenomenon is also exemplified by research examining post-conflict affiliation among competitors (Benenson and Wrangham 2016). The authors examined same-sex competitors, both male and female, and observed their behavior following competition to determine how long the competitors interacted with each other after the contest. Relative to females, males were significantly more likely to engage in post-conflict affiliation for extended periods of time. Men's willingness to move past the competitive interaction may function to promote coalitional solidarity. This solidarity is essential for helping a group pursue a focused goal in which group size is a key determinant of success.

Studies have also found a strong preference among young adolescent males to prefer same-sex peers with attributes associated with status within the peer group (Benenson 1990). Such attributes include a respect for authority, quality of work habits, athletic ability, academic ability, and whether they are a "fighter." Preference for such attributes may indicate a stronger proclivity for hierarchical systems of organization within groups that would enable greater efficiency while working toward a particular cause (i.e., war, competition, etc.).

Coalitional Functionality

When men form a coalition, group consensus/agreement reduces discontinuity and increases cooperation, which facilitates progress toward the coalition's agreed upon goals. Evidence that men seek to minimize the potential for disagreement can be seen in the behavior of men on the night before a war raid. At this time, men have been observed to banish women from the group to minimize whatever sexual conflicts might exist among the men in the coalition. Brown argues that females will inevitably create competition between the males of the group, thereby breaking down the trust within the group. Thus, excluding females may increase cohesion and cooperation among male members and therefore increase the probability of success in warfare.

Another driving force of men's behavior within a coalition is the fear of acting with cowardice, thus shaming themselves in the eyes of their comrades in arms (Browne 2001). This shame is an emotional tool used to encourage loyalty to the group. It also encourages risk-taking behaviors that increase trust among comrades. One's fear of cowardice may be particularly motivating given that perceived cowardice by one's group may carry severe costs. For example, refusal to participate in warfare may result in punishment, including ostracism from one's group (Boyd et al. 2003; Boyd and Richerson 1992). Similarly, when asked to judge the actions of unskilled versus cowardly male warriors, members of a nomadic pastoral society in Kenya

reported greater willingness to punish cowardice than lack of skill, including refusal to lend an animal or marriage to their daughters (Matthew and Boyd 2014).

Goldschmidt (1988) reviewed cultural influences on men's participation in raids and warfare in 27 non-state societies and concluded that there are strong systems of social rewards, and punishments, in place for warriors. Indeed, successful male warriors are often awarded high social status within one's group. For example, among the South American Yanomamö, men who kill another man in warfare are given the high honor of being labeled a "Unokai" and earn greater mating access as a reward (Chagnon 2013). Ultimately, risk taking and loyalty to a group in the context of intergroup conflict have tremendous potential for reproductive benefits, which motivates cooperation within a group under a variety of circumstances.

Conclusion

Males prefer large, cohesive, social groups of same-sex peers, whereas females generally prefer dyadic relationships. This preference among men may be best construed as a coalition-building mechanism that functions to promote men's success in intergroup warfare. When intergroup conflict occurs, men form coalitions that exclude women and fight to protect or gain reproductive resources. Such coalitions have served a significant evolutionary function in creating cohesive bands to fight and defend against outgroups in the struggle to advance the group's status in the social dominance hierarchy.

Definition

Same-sex friendships are lasting coalitions between individuals who are the same biological sex.

Introduction

Friendships are intriguing cross-species phenomena that clearly contribute to both fitness and survival. Friendships involve coalitions based on altruistic interactions over a long period of time. Unlike opposite-sex friendships, same-sex friendships are less likely to include sexual motives. Although affiliative bonding is common in a large number of species, humans may be unique in the extent to which this happens among unrelated individuals. The theories that have been used to explain same-sex friendships are mainly reciprocal altruism and kin selection, which will be reviewed briefly below.

Kin Selection and Same-Sex Friendships

Research that investigates proximate determinants of friendships has found that friends are genetically similar (Christakis and Fowler 2014), suggesting that friends are viewed as extended kin

(Brent et al. 2014). Women especially have the tendency to treat close friends as kin (Ackerman et al. 2007), which could be part of an evolved mechanism for establishing and maintaining close social bonds. During human evolution, ancestral women had high rates of migration from their natal groups, which could explain the importance of friends for women as a kind of a functional kin. When emotional closeness is high, altruism in friendships can be as strong as between genetically related kin. However, in order to flourish, friendships need more maintenance than kinships do. Therefore, friendships are not based on the same behavioral principles as relationships with kin are, and kin selection alone is insufficient in explaining evolution of same-sex friendships.

Reciprocity and Same-Sex Friendships

Although long-term collaborative relationships with non-kin can be explained by the theory of reciprocal altruism, friendships do not form a straightforward case. Friendships do not seem to involve keeping a tally of whether favors are reciprocated, which leaves room for cheaters to flourish (Silk 2003). On the other hand, an expectation of reciprocation in friends is higher than among siblings (Rotkirch et al. 2014). This suggests that friends are not completely exempt from the rules of reciprocation. In order to maintain reciprocation and deter cheating, friendships are characterized by high levels of trust and emotional closeness. Trust plays an important role in friendships not only in humans but also in our closest relatives, chimpanzees (Engelmann and Herrmann 2016). Thus, reciprocity in friendships requires high levels of trust and emotional closeness, and when these are lacking, there may be more “bookkeeping” in reciprocation of favors.

Conclusion

Friendships are a widely spread phenomenon in the animal kingdom, and the ability to form affiliative long-term bonds with unrelated individuals clearly has evolutionary benefits. Same-sex friendships can be explained by the theories of kin

selection and reciprocal altruism. Friendship selection may have a base in assortative choice for genetic similarity, which suggests that friends could be viewed as extended kin. Although close friendships do not involve conscious counting of favors, it is possible that reciprocity is maintained via high levels of trust and emotional closeness.

Definition

Same-sex friendship is a nonsexual and nonfamilial communal bond characterized by voluntary independence between two same-sex individuals.

Introduction

Friendship is a unique dyadic relationship that is not only cherished but also sought after for a variety of reasons in almost every culture studied. Not surprisingly, there is a word describing a relationship established outside the kin environment in nearly all cultures and languages. Even though some of these words share a common root with kin-relation words, they over time became uniquely associated with the idea of friendship (Krappman 1996).

One critical issue in defining friendship concerns the possible overlap with other relationships. The theorized lack of sexual relations between friends differentiates it from relationships specifically formed to address mate attraction and retention. Also, the idea of voluntary interdependence as one of the defining feature of friendship is essential for distinguishing relationships with kin from those involving nonkin. That friendship is psychologically, objectively, and subjectively different from kinship and that it is a nonfamilial bond is a critical distinction. The importance of this distinction is sometimes highlighted at the theoretical level (Park and Ackerman 2011) and frequently encouraged at the methodological level (Demir et al. 2015). Yet, our ancestors were likely to call friends those who were genetically related (Hruschka 2010), a tendency, albeit to a lesser degree, still observed in modern times. Also, when the friendship between two unrelated individuals exceeds a certain level of closeness, people consider the friend as part of the family by calling each other brothers or sisters. This prompted some scholars to postulate that people can be both kin and friends. From an empirical point of view, however, not differentiating friendship as a bond between nonrelatives from other relationships could hinder scientific progress in the understanding of the benefits and costs associated with this

cherished bond and create a problem in testing the utility of various theories explaining why and how we form and maintain friendships. Without proper definitions and differentiation, we might be studying the “friendships” between uncles, mothers and their offspring, and nonrelatives at the same time, while it is clear that these relationships serve different functions and roles.

Same-sex Friendships

One could generate a synthesis to define friendship from the myriad definitions reflecting the perspective of the Western world. Accordingly, friendship is defined as a nonsexual and non-familial communal bond characterized by voluntary interdependence between two individuals. The continuity of this voluntary independence promotes an unrestricted closeness that facilitates and promotes the experience and satisfaction of various provisions such as intimacy, affection, in/tangible mutual aid, companionship, self-validation, emotional security, and comfort to varying degrees. An evolutionary perspective would make a meaningful contribution to this list by highlighting some critical functions friends serve such as providing help to address mating-related issues and forming cooperative alliances. Yet, while some of the indispensable notions and provisions of Western conceptualization of friendship such as mutual aid is similar in every culture studied (Cohen 1966), the eloquent work by Hruschka (2010) showed that some of these features such as voluntariness of the bond, frequent socializing, and self-disclosure display significant variety across cultures and in some cases are absent.

Notably, there are different types and forms of friendships observed in various cultures such as inalienable, expedient, casual, and close friendships (Cohen 1966). These different forms of friendships vary on the level of closeness and support provided or received in the relationship. Inalienable friendship, for instance, concerns the institutionalization of the bond via rituals that serve the goal of conversion to a fictive kin. The conceptualization of same-sex friendship that

represents varying degrees of interdependence is similar to Cohen’s close friendship form.

Much of the literature has treated friendship as a same-sex phenomenon, specifically a bond between two males. This emphasis, sometimes romanticized, was evident in ancient societies and cultures and dominated the writings of classical philosophers. Although females were establishing and incurring the many benefits of friendships with other females, the empirical and literary attention to this unique dyadic experience is relatively recent.

Friendship usually involves same-sex peers, with the majority of adults’ friendship networks, and overwhelmingly best and closest friends, consisting of same-sex peers (Demir et al. 2015). Although people establish and maintain platonic opposite-sex friendships (OSFs), and incur benefits not available in same-sex friendships (e.g., the provision of insider perspective that entails learning about how the other sex feels and thinks), OSFs are perceived as gateways to sexual and romantic experiences, usually for heterosexual men. Indeed, the preferences for and selection of OSFs overlap considerably with mating strategies and preferences (Lewis et al. 2011).

Benefits and Costs of Same-Sex Friendships

In pursuing an understanding of same-sex friendships, an evolutionary perspective would address the puzzle of why friendships evolved in the first place and what functions they served. Hruschka (2010) argued that friendships served to address the “common adaptive problems of cooperation and mutual aid in uncertain contexts” (p. 10). Forming cooperative alliances with nonkin would have provided direct and indirect benefits linked to survival, adaptive problem solving (i.e., finding mates and retaining them, alloparenting), and well-being. Previous research has theorized friendships to be governed by reciprocal altruism, which is the expectation that each friend is contributing equally to the friendship. This involves keeping track of the other’s contribution, with failure to put in equal contributions resulting in conflict.

However, this view may not be useful to understand friendships. Specifically, in an interdependent bond where people show sincere concern for each other's well-being, a tit-for-tat exchange would not only be destructive and but also almost impossible to maintain. Besides, males and females do not generally report monitoring their friends' inputs and consider doing that as a violation of friendship (Park and Ackerman 2011). Instead, friendships have been viewed as being communal in nature and are governed by cooperative coalitions where support is provided on a need-by-need basis. Engaging in this communal relationship highlights the importance of being selective who one chooses as a friend (Tooby and Cosmides 1996). Given that costs arise in any given relationship (i.e., cheaters, freeloaders), individuals thus must limit their friendships to people who display deep engagement and are worthy of both tangible and intangible investments. The benefits of same-sex friendships, however, appear to balance or offset the costs, especially when one becomes irreplaceable (Tooby and Cosmides 1996). Becoming irreplaceable ensures that friends will be concerned with and invested in each other's well-being.

One benefit of same-sex friendships for both sexes concerns finding and retaining mates. Men and women appear to prefer establishing friendships with people who are desirable to the opposite gender; forming this relationship gives them access to more potential mates. This may explain why men tend to value instrumental characteristics (i.e., attractiveness, athleticism) in friendships (Lewis et al. 2011), while women seem to value physical attractiveness and interpersonal traits such as kindness (Vigil 2007). The benefit of gaining a larger mating pool from friendships does come at a cost: rivalry over mates. Both men and women experience feelings of rivalry with their friends over potential mates, with the less attractive friend reporting a higher amount of perceived rivalry. Furthermore, both sexes not only report more negative emotions when rivalry comes from a friend rather than a stranger, but they also will downplay their sexual promiscuity to avoid scaring off potential friends, with women being slightly more sensitive in these domains

than men (Bleske and Shackelford 2001). In terms of how these issues are addressed in friendships, it has been argued that men and women evolved to favor people who are not perceived as mating rivals for friends, and when these issues do arise in friendships, individuals may be forced to reevaluate whether the friendship is truly beneficial to them. Thus, being selective in friendships not only produces the benefit of mate selection but also minimizes the cost of mating rivalry.

Similarities and Differences in Males' and Females' Same-Sex Friendships

Given the universality of same-sex friendships, it is not surprising that men and women are similar to each other in terms of certain aspects of friendships (Hall 2016). For instance, propinquity, or mere proximity, is one factor contributing to the development of a friendship for both sexes. Also, both males and females value similarity in their same-sex friendships, and they are similar to their friends in a number of domains ranging from age to interests, personality, and physical attractiveness. Another domain in which males and females do not differ concerns the social meaning of the friendship, referred to as the deep friendship structure (Hartup and Stevens 1997). This is contrasted with the surface structure capturing the actual social exchanges in the friendship. Accordingly, males and females are on the same page about what friendship is, the rules governing friendship, and the value of having friends. Yet, differences arise in the way friendships are experienced between males and females, some of which could be explained by the fact that historically they were required to perform different tasks within their communities (i.e., hunting vs. gathering) and had different adaptive problems to address.

Male and female same-sex friendships differ on a number of domains, including intimacy and self-disclosure, friendship expectations, and stability. These differences can be prefaced with the common notion that female same-sex friendships are "face-to-face" relationships, while male same-sex friendships are characterized by "side-by-side" interactions (Wright 1982). In essence, women opt

to engage in more emotional experiences, while men strive for more shared experiences.

One well-established pattern in same-sex friendships is that males tend to have lower levels of intimacy and self-disclosure than females. Men spend less time talking with their best friends and more time engaging in activities with friends. Furthering this idea, men not only display less intimacy but also appear to sacrifice intimacy for a greater number of friendships. Furthermore, men report higher numbers of close and best friends, along with a desire to have more friends with less intimate behaviors (i.e., support). In contrast, females display the opposite trend: they opt for fewer, but more intimate, friends. Similarly, they also tend to engage in more self-disclosure and relational maintenance behaviors (i.e., tending to and being aware of each other's needs) than their male counterparts in their same-sex friendships.

Notably, sex differences in intimacy were observed across studies relying on different assessments of intimacy. Of course, one is not referring to an all-or-none issue here such that males do experience intimacy in their same-sex friendships but not to the extent females do. This suggests that males and females have a similar understanding of what intimacy is and how to achieve it in same-sex friendships. Rather, males do not prefer to engage in intimacy promoting behaviors in their same-sex friendships as much as females do. Males' avoidance of intimacy might be evolutionarily functional such that intimate disclosures to a same-sex friend might hurt their reproductive success in the case of the termination of the friendship (Shackelford and Buss 1996). Also, cultural norms and gender roles such as encouraging emotional restraint for men and homophobia toward gay men explain why same-sex friendships are less intimate and supportive among men than women (Bank and Hansford 2000). Although these constraints and concerns reinforce the belief that males might prefer to have less intimate friendships, they might not be content with this preference as research has shown that males ideally want to experience more intimacy and support in their same-sex friendships (Demir and Orthel 2011).

Despite lower levels of observable intimacy, male friendship persists. Male friendships not only display less reciprocity and intimacy than female friendships but also they appear to be more tolerant of their same-sex peers (Benenson et al. 2009). Also, these friendships appear to last longer and be more resistant to deterioration after conflict. These trends make sense, as research has found men to be less affected by aggression committed by their same-sex peers and are more likely to move past the conflict than women (Benenson et al. 2014). On the other hand, female friendships have been characterized not only by higher expectations of reciprocity and intimacy but also by shorter durations and more emotional conflict. The connection is clear; higher standards are more difficult to live up to, and thus failing to meet them might be more common. When expectations are not met, conflict may ensue.

Explaining Sex Differences in Same-Sex Friendships

From an evolutionary perspective, sex differences in same-sex friendships can be explained in number of ways. Evolutionary psychologists have theorized that the trends in male relationships evolved to better suit them for survival (Buss 2015), and one useful framework in which functions of male friendships can be understood is the structure of cooperative coalitions, or the alliance hypothesis (DeScioli and Kurzban 2009). This hypothesis, in essence, states that when three or more parties are competing for resources, forming an alliance with one of the other parties would mean that the members of the alliance have a better chance of getting more resources than the lone third party. This hypothesis differs from other exchange theory models in one important way: it is not based on equal reciprocity, but rather the expectation that one will provide support in a time of need. This may explain why in general men tend to have lower expectations of reciprocity and intimacy than women.

Early human groups followed the hunter-gatherer model, where men typically did the hunting of big game and fighting with other groups.

Although researchers have described sex differences in expectations of reciprocity as slight (Hall 2016), it is possible they served an important role. Considering that male relationships tend to have high levels of competition (Buss 2015), forming a social structure in which competition is replaced with cooperation would have been adaptive to acquiring more food and security. These slight differences in expectations, which promote stable relationships, may have played an influential role in ensuring the continuity of friendships and social structures in ancestral communities. This is coupled with the findings of Vigil (2007), who found men to report higher levels of cooperation. These lower expectations and greater willingness to cooperate with nonkin may explain why men report a larger network of friendships. This idea is corroborated by a recent study that found that men prefer to form larger coalitions with other males, while females prefer intimate, dyadic relationships (David-Barrett et al. 2015). This may serve to explain why males not only have larger friend groups (i.e., more allies) but also why they value traits like athleticism and power. Befriending individuals with these traits would have increased their collective strength and status.

Female friendships are theorized to have functioned as a means of developing supportive networks and protection. The slightly higher expectations of reciprocity from females may have evolved to facilitate survival. Historically, females mated outside of their kin networks, throwing them into a community of strangers. In stressful and harsh situations like this, they needed to be skilled in establishing supportive relationships with other nonkin, which would have provided them and children with safe and supportive environments. When presented with stress or conflict, males typically exhibit a fight-or-flight response; females, however, opt for a “tend-and-befriend” strategy (Taylor et al. 2000). Considering females were typically assigned the role of caring for children, choosing to engage a threat or uncertain situation with a fight-or-flight response could have endangered their children or other children they were caring for. Thus, creating a strategy to manage stress that involves both tending to their children and befriending other

women to create a protective social network would have been a more adaptive survival strategy for females and their children. This strategy may also explain why they have higher expectations in reciprocity and self-disclosure; women who were able to live up to these higher expectations would have been more likely to reliably provide support in times of need.

Establishing these relationships and meeting high expectations would have created an environment where they both supported and were supported by other women in domains such as child care and would have had a protective network from other males. The practice of alloparenting would have provided the benefit of shared parenting responsibilities between women; however, this placed children in a position to be harmed by other women. These stricter standards for friendships would have ensured that the women they invested personal trust and resources in would be able to provide support and safety for them. While men formed alliances to gather resources, women tended to rely much more on each other for their well-being. Thus, higher expectations of friendship behaviors may have allowed them to parse out which individuals were both beneficial and willing to engage in reciprocal support for them. This may explain why these friendships tend to display more conflict and early termination, because not meeting expectations may have alluded to unreliability in times of need or a lack of investment in each other’s well-being.

Same-Sex Friendship and Well-Being

From an evolutionary perspective, another function of same-sex friendship would be its contribution to survival by promoting the mental and physical health of the individuals. To the extent that the paradox created by modern living is addressed by establishing deeply engaged friendships as opposed to ambivalent friendships (Tooby and Cosmides 1996), males and females likely incur additional benefits from their same-sex friendships. For instance, positive same-sex friendships might be the antidote to feelings of loneliness and alienation, concerns prevalent in modern life. Although social integration and diversity of relationships have been

shown to predict health, longevity, and survival (Holt-Lunstad 2016), the specific role of same-sex friendships is not clear. However, since same-sex friendship experiences are robust correlates of happiness, and happiness promotes longevity and physical health (Diener and Chan 2011), it is possible that same-sex friendships add to the prediction of survival and physical health. As for happiness, although it is argued that social relationships would be more important for females than males, research on adult same-sex friendships has found that both sexes benefit similarly from the quality of their same-sex friendships (Demir et al. 2015).

Conclusion

The existence of same-sex friendships in every culture studied suggests that it is a valuable relationship. Ostensibly one should be careful in choosing a same-sex friend for it entails costs related to reproductive success. Yet both sexes establish and maintain interdependent same-sex friendships and reap the many benefits this cherished bond entails. Although the internal constitution of the friendships might be different for males and females, the ultimate beneficial impact is the same. Future research has the potential to enhance our understanding of how, when, and why same-sex friendships are beneficial.

Definition

The intentional killing of someone in which the perpetrator and victim are the same-sex, that is, both are male, or both are female.

Introduction

There are four combinations of perpetrator-victim relations by sex: men killing men, men killing women, women killing men, and women killing women. The proportion of homicides that occur in each of these categories is not equal, contrary to the expectation when random occurrence is hypothesized in large populations. Rather, the majority of homicide cases consist of men killing other men. When you look specifically at same-sex homicide, male-male homicide occurs much more frequently than female-female homicide, especially between unrelated persons, across many different societies and cultures, and spanning long periods of time (Daly and Wilson 1988). This entry will discuss an evolutionary explanation for this phenomenon.

Violence and Sexual Selection

Most homicides occur as a result of a conflict between individuals. Homicide cases where victims were randomly chosen without any particular personal conflict are very rare. The nature of conflict is variable, depending on the relationship among the people involved: whether they are families, lovers, or unrelated acquaintances. Common motives of men killing unrelated men are predominantly competition over social status, face, pride, and reputation, as well as conflict over more tangible material resources. Despite the seeming triviality of these motivations, more than half of male-male homicides across many different societies are precipitated by a conflict over status or reputation. Evolutionary psychology provides a functional explanation for why this behavior occurs and why it is most common among men.

Key to understanding the sex differences in the rates of same-sex homicide are the theories of parental investment and sexual selection (Trivers 1972). Male's obligatory investment of time and energetic resources in offspring is quite minimal, whereas the required investment of females is extensive. As a result, men are capable of having many more offspring in their lifetime than are

women. Women are therefore the limiting resource that constrains men's reproductive success. The consequence of this is that there will be greater variability in the reproductive success of men compared to women. This is amplified by the fact that most small-scale, traditional societies practice polygyny. Moreover, many hunter-gatherer societies that are regarded to be "egalitarian" permit men to have extra-wives. Thus, men must compete with other men for access to mating opportunities or risk reproductive oblivion.

This competition may take the form of direct competition for access to a female or competition for resources, status, and prestige that will indirectly increase reproductive success by increasing one's appeal to females. Therefore, winning competition should have been a critical issue for men during the long history of human evolution. Material resources such as cattle or land are not necessarily the purpose of gain per se but ultimately a means to increase reproductive success. Under these conditions, men will be willing to take large risks in competitive situations because the alternative strategy of opting out of competition drastically reduces one's chances of acquiring reproductive opportunities (Daly and Wilson 1990). From this perspective, homicide can be viewed either as a by-product of adaptations for engaging in competition or as a direct adaptation for removing intrasexual rivals competing for the same mates.

Cases in women killing other, unrelated women are quite rare. However, this does not mean that women do not engage in intrasexual competition. Given women's large investment in offspring and their limited lifetime reproductive output, there is less incentive for women to compete with each other in order to increase the quantity of mating opportunities. Rather, women are likely to compete with one another in order to gain and maintain access to the highest quality mates, for example, those best able to ensure the survival of the mother and her offspring, those with high genetic quality, and those with ample resources to help provision of offspring.

However, because their own survival is essential and more important to infant survival than father's survival, women have lower threshold

for fear in situations that pose bodily injuries and higher threshold for employing physical violence in a competitive situation than men. Engaging in high-risk violent competition poses a serious threat to their reproductive fitness (Campbell 1999; Sear and Mace 2008).

Consequently, women adopt more subtle, indirect tactics such as gossip and social exclusion, thereby attacking the competitor without the danger of physical violence. Because a woman's own survival is critically important for her reproductive success, it is reasonable to assume that there has been a strong selection for women to use indirect tactics for intrasexual competition that would unlikely to result in personal injury or death (Campbell 2006). Considering this, the relative rarity of same-sex homicide among women is consistent with evolutionary theorizing.

Conclusion

Male-male homicide occurs much more frequently than female-female homicide, especially among unrelated individuals. This is fundamentally due to the sex difference in parental investment, leading to that male-male competition for the access to females being much more stronger than female-female competition. From this perspective, homicide can be viewed either as a by-product of adaptations for engaging in competition or as a direct adaptation for removing intrasexual rivals competing for the same mates. This does not mean that there is no competition among women; rather, there is a great deal of competition among women for access to high-quality men who are willing and able to provide parental investment. However, because women's own survival is critical for their reproductive success, women tend to avoid risking bodily injury, resulting in lower occurrence of female-female homicide.

Definition

Same-sex relationships are intimate affiliations between individuals of the same chromosomal

sex and/or gender that typically share homogeneous characteristics such as age and social status.

Introduction

The formation of same-sex relationships evolved to provide a context for humans to engage in reciprocal interchanges of resources with and learn sexually specialized behaviors from conspecifics. Same-sex relationships also serve as the ecological context in which *intrasexually* selected characteristics are expressed and moderate certain social fitness outcomes.

Evolutionary Origins

The social nature of humans consists of sexually specialized cognitive and behavioral adaptations that are developed and expressed in the context of and ultimately function for regulating same-sex relationships. These relationships evolved in humans and other socially dependent animals for extracting reproductively indirect resources, such as protection, shared effort, and sociopolitical opportunities, from the types of conspecifics that are most likely to reciprocate such resources.

Adaptive Significance

Formation of same-sex relationships in humans enhances survival and reproductive success by providing the ecological context in which characteristics that have been selected by intrasexual (within-sex) fitness pressures are learned and refined. Same-sex relationships also enable individuals to extract ecologically valid resources from the types of social affiliates that are most likely to reciprocate such resources.

Homophilic Peer Preferences

Same-sex relationships are usually formed among people that share similar characteristics such as

age, physical features, and social status. Homophilic peer preferences ultimately facilitate the formation of alliances between individuals with similar *reciprocity potential*, or perceived value to other people, by creating an opportunity in which both social agents can reciprocally benefit through mutual exploitation (Vigil 2007).

Sex Differences in Communication Styles

Humans engage in specialized communication styles for interacting with either males or females. These differences reflect the disproportionate use of behavioral advertisements of the capacity and trustworthiness components of human reciprocity potential for regulating different types of peer network structures (Vigil 2009). While men tend to form larger and more fluid peer networks and express higher levels of behaviors that demonstrate *immediate* capabilities, females tend to form smaller, more intimate networks and express higher levels of behaviors that demonstrate *continuous* reliability. These distinct sociorelational styles are comprised of what are conventionally referred to as “dominant” and “submissive” social behaviors, respectively.

Conclusion

Formation of same-sex relationships facilitates fitness and reproductive success in humans by exposing individuals to other social agents that are most likely to engage in reciprocal altruism. These specialized and functional forms of affiliation also provide the context in which certain sexually selected characteristics are developed and expressed. To date, the form and function of same-sex relationships have been linked to the development and expression of numerous life history traits, physical traits (Vigil et al. 2015), perceptual responses (Vigil et al. 2014), social behaviors (Vigil 2008), self-descriptions (e.g., self-esteem; Vigil et al. 2011), and medicine, including the expression of disease, pain (Vigil and Coulombe 2011; Vigil et al. 2013), health promotion behaviors, and the manner in which

people are evaluated and treated by health care professionals (Vigil and Alcock 2014).

Definition

Bullying is a behavior used to intentionally cause harm on less powerful individuals to obtain tangible, social, and reproductive resources (Volk et al. 2014). Same-sex school bullying includes intrasexual bullying, when boys bully boys and girls bully girls in order to achieve these goals. Often, same-sex bullying behaviors occur outside of the classroom setting, including school hallways, washrooms, and lunchrooms, where there may be less adult supervision (Kasen et al. 2004). Under specific school ecologies, same-sex school bullying may be more adaptive for children and adolescents.

Introduction

Same-sex school bullying may serve adaptive functions for children and adolescents. This may be why a significant proportion of youth, anywhere from 30 % to 40 %, are involved in school

bullying as the perpetrator (15 %), victim (14 %), or bully-victim (i.e., individuals who are both perpetrators and victims; 4.4 %; e.g., Espelage and Holt 2007; Hymel and Swearer 2015). School bullying peaks during the transition from middle to high school (Juvonen and Graham 2014), suggesting that bullying may serve more benefits than costs during this time period. The benefits of bullying during this developmental period may be a result of two key social changes. First, there are many new peers at the start of high school, which encourages the reformation of peer networks (Juvonen and Graham 2014; Pellegrini and Long 2002). Second, adolescence coincides with sexual development, which may heighten the desire for dating and mating relationships. Therefore, school bullying may serve adaptive purposes during these two important social changes.

Goals of Same-Sex School Bullying

Adolescents may strategically use same-sex school bullying for three primary goals: (1) obtain material resources, (2) establish dominance among same-sex peers, and (3) attract opposite-sex peers for reproductive opportunities (Volk et al. 2014). Several studies support these goals of same-sex school bullying. For instance, adolescent bullies often are high in social status with same-sex peers, especially when targeting victims who were disliked by other same-sex peers (e.g., Veenstra et al. 2010), demonstrating dominance and status goals. In addition, bullies often start dating and have more sexual partners during adolescence than nonbullies (e.g., Volk et al. 2015), demonstrating reproductive opportunities. While these studies demonstrate that the functions of same-sex school bullying may be the same for both sexes, the mechanisms and behaviors used by boys and girls to achieve these resources, status, and mates may differ. For example, Dijkstra et al. (2007) found adolescents have different criteria for same-sex peer acceptance and rejection in comparison to cross-sex peer acceptance and rejection. Boys are more accepting of boys and girls who show prototypical “boy” behaviors, while girls are more accepting of girls and boys

show prototypical “girl” behaviors. However, within both sexes, same-sex peers who showed prototypical cross-sex behaviors were more likely to be rejected. Thus, at a developmental period when status with same- and cross-sex peers is significant, the criteria to achieve acceptance and status may differ intrasexually. Evolutionary theory may help explain sex differences in the way adolescents use same-sex bullying as a tool to achieve material, social, and sexual resources.

Parental Investment and Sexual Selection

Differences in reproductive variability may explain why there may be intrasexual variation in school bullying strategies for adolescent boys and girls. According to the parental investment theory (Trivers 1972), females are the higher investing sex when it comes to parenting and offspring survival. Since females are often the primary caregivers for human offspring, they directly invest more resources per offspring including feeding and guarding, in comparison to males. As a result of the unequal parental investment, the sexual selection theory (Archer 2009; Daly and Wilson 1998) explains that there are different selection pressures for males and females. While males’ reproductive success is dependent on access to willing females, females’ reproductive success is dependent on choosing the best suiting male (Trivers 1972). Therefore, although the goals of bullying may ultimately be the same for all adolescents, given the differences in reproductive roles, it is logical for same-sex bullying to differ in behavior and strategies in adolescent boys when compared to girls.

Same-Sex School Bullying in Boys

Since boys have to compete with other boys for access to girls, boys may have more benefits when engaging in overt competition in comparison to girls. Indeed, sex differences in forms of bullying peak during early adolescence (Archer and Coyne 2005). When compared to other forms of aggression, the largest sex difference is for physical aggression (e.g., hitting, punching) in favor of boys (Archer 2004). Moreover, multiple studies on adolescent bullying found support for this sex difference in physical bullying (Hong and

Espelage 2012; Hymel and Swearer 2015). Overt physical bullying may be adaptive to boys as it may increase reproductive fitness through two key methods.

First, physical behaviors allow boys to compete with other boys to establish status among same-sex peers (Archer 1996). By targeting a weaker victim through the use of physical bullying, boys can secure a high, powerful role in their peer hierarchy (Ellis et al. 2012). Physical bullying behaviors can eliminate same-sex rivals who are competing for the same resources, while deterring future rivals by signaling costs to engaging in physical conflict (Volk et al. 2014). Rodkin and Berger (2008) support this idea when they found adolescent boys who bully weaker boys were more popular by their peers. Moreover, Sijtsema et al. (2009) found that boys who bully had high status goals. As a result of establishing status, boys may then have increased access to material resources, such as food, money, or school territory (Volk et al. 2014). Therefore, the first way physical bullying increases reproductive success for boys is by enhancing one’s own status and access to material resources at the expense of other same-sex peers.

The second way physical bullying can increase reproductive success is by demonstrating features that may be attractive to opposite-sex peers (Archer 1996). Given that girls are the selective sex when it comes to picking mates, boys may use physical bullying as a method to demonstrate toughness and bravery (Archer 2009; Benenson 2009; Ellis et al. 2012). For example, Rodkin et al. (2006) found that adolescent girls were more likely to nominate boys they thought were tough as being cool in comparison to nontough boys. Exhibiting physical strength may signal the ability to provide material resources and protection to offspring, which may encourage girls to pick them as a mate (Ellis et al. 2012). Thus, boys may use physical bullying to both display their resources and seek girls as a specific type of resource. Pellegrini and Bartini (2001) support this idea in a study on bullying among adolescent boys. As these boys aged, physical bullying was associated with increased dominance, popularity, and dating. Similar results were found by Veenstra

and colleagues (2010) as boys who bullied other boys were rated in high acceptance by girls. Therefore, the second way physical bullying increases boys' reproductive success is by attracting girls who may select them as a mate. Bullying may also increase reproductive success for girls, but the mechanisms and behaviors may differ from boys.

Same-Sex School Bullying in Girls

Girls engage in less overt competition when compared to boys. This may be due in part to different selective pressures. According to the parental investment and sexual selection theories, females are more discriminating than males when selecting a mate (Trivers 1972). This may be because reproduction is a costly event both biologically during pregnancy but also after birth. Human offspring are born dependent on mothers as primary caregivers for resources including safety, warmth, and food (Hrdy 1999). In fact, survival for the first 2 years of an infant's life is often dependent on the survival of their mother as documented in multiple societies (Sear and Mace 2008). Thus, it is in a female and her offspring's best interest to expend resources on parenting as opposed to overt sexual competition (Trivers 1972; Hrdy 1999). As a result, females are more selective than males in choosing a mate who demonstrates not only his ability to contribute healthy genes but also his ability to provide material resources that could aid maternal care (Hrdy 1999). However, this does not mean that adolescent girls do not engage in bullying at all. Instead, girls may strategically use covert bullying behaviors through two important methods.

First, indirect bullying behaviors such as social exclusion and rumor spreading may be advantageous to adolescent girls, because they can reduce the attractiveness of competitors, without expending physical resources. While boys may use physical bullying to demonstrate their own ability to provide resources, girls may strategically use indirect bullying as a way to show how rivals may not be able to provide maternal resources (Archer and Coyne 2005). Girls' indirect behaviors often denigrate features that are ideal to boys, such as an attractive physical

appearance and lower sexual promiscuity (Geary 1999). These qualities are often targeted since they signal reproductive health to boys. Thus, girls who allow sexual access to boys would threaten and reduce other girls' power to be selective when choosing a mate (Benenson 2013; Campbell 2004). For example, in a study by Vaillancourt and Sharma (2011), undergraduate women perceived other women who dressed attractively as more negative and threatening. Therefore, these individuals may make for a logical target to bully among girls. Leenaars et al. (2008) support this idea when they found that adolescent girls who were more physically attractive and had more dating and sexual partners were at a higher risk for indirect victimization from other girls. Similarly, Rodkin and Berger (2008) found that victimized girls were rated higher in peer-valued characteristics such as physical competence and social preference, in comparison to victimized boys. This suggests that while boys victimize weaker boys, girls victimize girls that may have some resources and pose a threat. Consequently, strategically excluding or gossiping about girls' appearance and sexuality within girls' close peer networks may subtly reduce the mate value of rivals to boys, while increasing their own status, dominance, and value.

Thus, similar to boys, the second way engaging in same-sex school bullying may increase reproductive success for girls to enhance one's own status and dominance in same-sex peer networks. However, the way girls establish dominance may be different than that of boys. While boys use physical behaviors to establish dominance, girls use social knowledge such as personal information and stories about their peers, as demonstrated through indirect bullying to establish status. For example, indirect bullying was associated with social knowledge, which reinforced girls' membership in a powerful social group (Owens et al. 2000). Moreover, Coyne et al. (2006) found that when compared to boys, girls reported indirect forms of bullying as more harmful to their social relationships. Therefore, appearing to have a lot of social resources may boost status and social power among other girls.

In turn, being a member of a powerful girl social group may lead to accessing additional material resources, as well as high-status boys who girls can then choose as a dating or mating partner. Pellegrini and Long (2003) and Sijtsema and colleagues (2009) support this idea as they found higher levels of aggression and bullying in adolescent girls were associated with dating and popularity, respectively. Additionally, covert bullying has the benefit of potentially remaining anonymous to the victim, thereby decreasing opportunities for the victim to retaliate (Campbell 2004). Therefore, indirect bullying may be adaptive for adolescent girls since they tarnish the reputation of competitors, allow girls to remain anonymous to the victim, and indirectly enhance their own status and mate value.

Conclusion

Taken together, it is evident that adolescents use same-sex school bullying during times of social transition and uncertainty as an adaptive tool to increase status, power, and access to resources. Adolescents may use same-sex bullying to increase access to resources, secure a position within their same-sex peer networks, and also attract high-status opposite-sex peers. However, the specific behavior and mechanism may vary within each sex in order to maximize benefits and minimize costs. Boys may benefit from using overt bullying behaviors to appear tough and strong to both rivals and prospective mates. However, girls may benefit from covert indirect bullying behaviors that degrade rivals while increasing their own status and value. The evolutionary underpinnings reveal an important aspect that should be targeted in anti-bullying school initiatives.

Few studies and interventions focus on the heterogeneity of bullying, including sex differences in bullying behaviors and peer network dynamics (Volk et al. 2012). Interventions might affect intra- versus intersexual bullying differentially. Therefore, when targeting intrasexual bullying, interventions targeting a school's ecology should also take sex dynamics into consideration, such as the ratio of boys and girls in a classroom, grade, or school

(Ellis et al. 2012). Moreover, by focusing on the evolutionary sources of bullying behaviors, interventions may focus on altering the cost-benefit ratio for a given bullying behavior for both boys and girls, where bullying behaviors are not rewarded with any resources (Ellis et al. 2012). Therefore, existing interventions may want to incorporate methods to counter intrasexual competition. For instance, the KiVa intervention focuses on bystander interventions so that bullies are not provided with social rewards from peers (Salmivalli et al. 2010). In addition, the Meaningful Roles intervention provides prosocial strategies for adolescents to achieve their goals, without resorting to bullying (Ellis et al. 2015). Therefore, by including ways for bystanders to intervene in same-sex school bullying or providing alternative prosocial methods for adolescents to achieve status among same- and opposite-sex peers may help reduce bullying. In conclusion, school antibullying initiatives should be mindful of the motivations, costs, and benefits behind same-sex bullying, as well as intrasexual peer-network dynamics, in order to effectively intervene.

Definition

Sexual behavior between individuals of the same sex.

Introduction

An estimated 3.5 % of adults in the United States (US) identify as lesbian, gay, or bisexual (LGB), which amounts to more than 8 million people (Gates 2011). An even larger percentage reports that they have engaged in same-sex sexual behavior (8.2 %) or acknowledges at least some same-sex attraction (11 %) (Gates 2011). Further, studies have demonstrated that sexual attractions, behaviors, and identities can change over time and across situations, especially for women (e.g., Diamond 2008). This indicates that same-sex sexual behavior transcends self-identification as LGB, and it underscores the widespread relevance of same-sex sexual behavior. This entry describes sexual behavior between individuals of the same sex, including the specific sexual behaviors that they engage in, the prevalence rates of these behaviors, and their relative risks for HIV. Given the brief nature of this entry, the focus is on cisgender individuals (those whose current gender identity is consistent with their sex assigned at birth). Less is known about the sexual behaviors of transgender individuals (those whose current gender identity is not consistent with their sex assigned at birth), and most research on this topic is focused on sexual risk behavior (e.g., Feldman et al. 2014).

Types of Same-Sex Sexual Behavior

In order to describe the types of sex that same-sex partners engage in, it is first necessary to define sex. To do so presents a challenge, as there is not unanimous agreement about what constitutes sex. Since 1999, researchers have studied people's definitions of sex by asking them if they consider various behaviors to be sex. Across studies, people generally agree that vaginal and anal intercourse are sex (for a review, see Horowitz and Spicer 2013). Horowitz and Spicer (2013) provided evidence for a hierarchy of sex acts (from most to least constitutive of sex), which included intercourse (vaginal and anal), other genital contact (oral and manual stimulation, stimulation by a sex aid), breast/nipple contact (oral and manual stimulation), and kissing. There is also some evidence that lesbians and gay men think differently about what constitutes sex, such that lesbians consider genital stimulation to be more constitutive of sex than heterosexuals do (Horowitz and Spicer 2013) and gay men consider anal intercourse to be the behavior that constitutes sex the most (Hill et al. 2010). Given disagreement about what constitutes sex, behavioral definitions of sexual acts have the greatest potential to facilitate clear communication about sex.

Most of the sexual behaviors that same-sex partners can engage in are the same as those that different-sex partners can engage in. However, certain sexual behaviors are exclusive to either same-sex or different-sex partners, and others are commonly associated with same-sex partners even though different-sex partners can engage in them as well. Vaginal intercourse is the one behavior that is exclusive to different-sex partners, and it involves one person inserting their penis into another person's vagina. In contrast to vaginal intercourse, most sexual behaviors are not exclusive to same-sex or different-sex partners (e.g., manual and oral stimulation, anal intercourse). Manual stimulation can be a solo or partnered activity. When it is engaged in as a solo activity, it involves one individual stimulating their own genitals (penis, vagina, or anus) using their fingers or hand and it is referred to as masturbation. When it is engaged in as a partnered

activity, it can take the form of masturbating in the presence of a partner or one person using their fingers or hand to simulate another person's genitals. Manual stimulation is colloquially referred to as jerking/jacking off or a hand job (when performed on a man) and fingering (when performed on a woman). A specific type of manual stimulation is fisting (anal or vaginal), which involves inserting four or more fingers into the anus or vagina. Although men and women can both engage in fisting, it is commonly thought of as a behavior that gay men engage in.

Oral sex involves one person using their mouth to stimulate another person's genitals. It is referred to as fellatio when performed on a man and cunnilingus when performed on a woman. Colloquially, it is referred to as giving a blow job (when performed on a man), eating someone out (when performed on a woman), and going down on someone or giving head (when performed on either a man or a woman). Anilingus (or rimming) is a specific type of oral sex, which involves one person using their mouth to stimulate another person's anus. Anal sex involves one person inserting their penis into another person's anus. Similar to fisting, anal sex is typically thought of as a behavior that gay men engage in, even though men and women can engage in it with each other as well. Scissoring is the one behavior that is exclusive to female same-sex sexual partners, and it involves one person rubbing their own genitals against another person's genitals. Finally, many people use sex toys (e.g., vibrators, dildos) to stimulate their own or their partner's genitals.

Prevalence Rates Among Men

It is challenging to estimate how common it is to engage in specific sexual behaviors, especially to do so for different sexual orientation groups, for several reasons. First, few population-based surveys assess sexual behaviors and the ones that do vary in how they define the behaviors and the time frames in which they are measured. Second, sexual orientation is operationalized differently across studies, with some studies comparing

individuals who self-identify as heterosexual versus LGB (e.g., Dodge et al. 2016) and others comparing individuals who report sex exclusively with men, sex with men and women, and sex exclusively with women (e.g., Mercer et al. 2007).

Dodge et al. (2016) reported rates of sexual behaviors among men in the USA using data from the 2012 National Survey of Sexual Health and Behavior. All of the rates reported in this section are based on those data unless otherwise noted. They found that sexual behavior was concordant with self-identified sexual orientation for most people. Most heterosexual men reported past-year sex with women only (75.1 %) compared to men only (1.0 %), both women and men (0.3 %), or not being sexually active (23.6 %). Similarly, most gay men reported past-year sex with men only (84.9 %) compared to both women and men (2.4 %) or not being sexually active (12.7 %). Although most bisexual men reported not being sexually active in the past year (39.7 %), a slight majority of those who were sexually active reported past-year sex with both women and men (24.8 %) compared to women only (22.2 %) or men only (12.4 %).

Self-stimulation, or masturbation, was common among men, regardless of sexual orientation (Dodge et al. 2016). The majority of men reported solo masturbation in their lifetime (91.5 % of heterosexual men, 99.7 % of gay men, and 100.0 % of bisexual men). Further, most gay and bisexual men reported solo masturbation in the past month (85.5 % of gay men and 93.6 % of bisexual men), whereas only 56.9 % of heterosexual men reported solo masturbation in the past month. Lifetime masturbation with a partner was also common among gay and bisexual men (94.0 % of gay men and 79.5 % of bisexual men), but it was less common among heterosexual men (51.9 %).

The majority of gay and bisexual men reported lifetime oral sex with a male partner (99.2 % of gay men and 90.3 % of bisexual men), whereas only 5.4 % of heterosexual men reported lifetime oral sex with a male partner. The majority of heterosexual and bisexual men reported lifetime oral sex with a female partner (86.8 % of heterosexual men and 92.5 % of

bisexual men), whereas only 34.8 % of gay men reported lifetime oral sex with a female partner. Most heterosexual and bisexual men reported lifetime vaginal intercourse (87.9 % of heterosexual men and 78.1 % of bisexual men), whereas only 28.4 % of gay men report lifetime vaginal intercourse. Most gay and bisexual men reported lifetime insertive anal intercourse (83.3 % of gay men and 74.8 % of bisexual men) as well as lifetime receptive anal intercourse (90.0 % of gay men and 65.7 % of bisexual men). In contrast, 32.7 % of heterosexual men reported lifetime insertive anal intercourse and 2.8 % of heterosexual men reported lifetime receptive anal intercourse. Finally, most gay and bisexual men report lifetime sex toy use either during solo or partnered masturbation (Rosenberger et al. 2012). In a large sample of gay and bisexual men, the most commonly used sex toys were dildos and butt plugs (62.1 %), which refer to objects designed to be inserted into the vagina or anus for sexual stimulation. Among those who had used dildos or butt plugs, most reported use during solo masturbation (89.4 %) followed by use during sexual foreplay with a male partner (69.4 %) and use during sexual intercourse with a male partner (66.5 %).

Prevalence Rates Among Women

While the prevalence rates of sexual behaviors among men in the USA have been reported separately for different sexual orientation groups (Dodge et al. 2012), the same data have not been reported for women. However, using data from the National Survey of Sexual Attitudes and Lifestyles, Mercer et al. (2007) reported rates of sexual behaviors among women in Great Britain. They compared the rates of sexual behaviors among women who reported sex exclusively with men (heterosexual), women who reported sex with men and women (bisexual), and women who reported sex exclusively with women (lesbian). Of note, this entry uses the terms “heterosexual,” “bisexual,” and “lesbian” to refer to these groups for convenience, but the groups were based on the sexual behavior that the women had engaged

in. All of the rates reported in this section are based on those data unless otherwise noted.

In this sample, 9.7 % of the women reported same-sex sexual experiences and 11.2 % reported sexual attraction, at least in part, to women. Past-month masturbation was most common among bisexual women (68.9 %), followed by lesbians (59.7 %) and heterosexual women (36.6 %). Among women who reported past-year sex with a man, most had engaged in vaginal sex (98.3 % of heterosexual women and 96.2 % of bisexual women), oral sex (85.4 % of heterosexual women and 94.8 % of bisexual women), and other genital contact (e.g., stimulation by hand) (81.5 % of heterosexual women and 95.2 % of bisexual women). In contrast, fewer had engaged in anal sex (12.1 % of heterosexual women and 26.9 % of bisexual women). Among women who reported past-year sex with a woman, most lesbians had engaged in oral sex (80.3 %) and other genital contact (92.7 %), whereas approximately half of bisexual women had engaged in oral sex (53.5 %) and other genital contact (60.9 %). Similar to gay and bisexual men, the majority of lesbians and bisexual women report lifetime vibrator use (86.0 %), including use during solo masturbation (80.9 %) or with a female partner (76.3 %) (Schick et al. 2011).

Risk for HIV

According to the Centers for Disease Control and Prevention (CDC 2016), the primary methods of HIV transmission in the USA are anal or vaginal sex (with someone who has HIV without using a condom or taking medicines to prevent or treat HIV) and injection drug use. In regard to sexual transmission, anal sex is the highest-risk behavior and vaginal sex is the second-highest-risk behavior. Of note, receptive anal sex is higher risk than insertive anal sex, but transmission can occur in either position. The risk of HIV transmission through oral sex is extremely low, with risk being highest for fellatio. Gay and bisexual men have the highest rates of HIV in the USA, whereas female-to-female transmission of HIV is rare.

Conclusion

People generally agree that vaginal and anal intercourse are sex, but there is disagreement about whether other behaviors constitute sex. Given that different behaviors are associated with different degrees of risk for HIV, definitional precision is of utmost importance. This may be especially true for same-sex sexual behavior, because LGB individuals think somewhat differently about sex compared to heterosexuals. Although sexual behavior is largely concordant with self-identified sexual orientation, there are more people who engage in same-sex sexual behavior or who report same-sex attractions than people who identify as LGB. As such, same-sex sexual behavior is relevant to individuals regardless of their self-identified sexual orientation.

University, Halifax, NS, Canada

Definition

An influential anthropologist working across multiple disciplines to contribute to our evolutionary understanding of female human and nonhuman primate behavior. Author of *The Woman That Never Evolved*; *Mother Nature: A History of Mothers, Infants and Natural Selection*; and *Mother and Others: The Evolutionary Origins of Mutual Understanding*.

Introduction

Sarah Blaffer Hrdy is a leading evolutionary anthropologist and primatologist who has significantly influenced numerous disciplines including evolutionary psychology, evolutionary biology, anthropology, primatology, developmental psychology, and women's studies. Her groundbreaking theorizing is based on systematic observations, comparative studies, historical documentation, and people's lived experiences, such that it bridges traditional disciplinary boundaries. Her work spans many topics that collectively remind scholars that individual fitness is key when understanding behavior. She is an award-winning scholar; her most notable achievement to date is being the recipient of the National Academy of science Award 2014 for Scientific Reviewing. With this award, she was recognized "for her insightful and visionary synthesis of a broad range of data and concepts from across the social and biological sciences to illuminate the importance of biosocial processes among mothers, infants, and other social actors in forming the evolutionary crucible of human societies." She is most noted for her meticulously researched books, which are also written "with the grace of a novelist" (van Schaik and Silk 2013).

Personal Biographical History

Sarah Blaffer Hrdy completed her undergraduate degree with *summa cum laude* distinction at Radcliffe College (at that time, the woman's part of Harvard) with a major in anthropology. Her undergraduate thesis was on h'ik'al, a bat-like demon of the Maya-speaking Zinacantan. H'ik'al had a tendency toward mischief and unrestrained sexuality, and the thesis was published in 1972 (and in paperback in 2012). In this cultural anthropological study, she explored other myths as well, ultimately leading to an analysis of regulation and enforcement of cultural norms, and specifically sex roles.

From here, Hrdy went on to Stanford and audited a course by biologist Paul Ehrlich, where he discussed challenges resulting from human population growth and problems associated with overpopulation. This material called to her mind a comment during one of her undergraduate primate behavior courses by Irven Devore at Harvard. Devore had mentioned that among Hanuman langur monkeys (*Semnopithecus entellus*) in India, males commit infanticide when living in high population densities (Sridhar 2016). She transferred to Harvard where she studied male langur infanticide in various habitats. From there, she became interested in other facets of langur behaviors such as female intrasexual competition, bonding, and shared care of infants (Sridhar 2016). These were exciting moments for Life Sciences at Harvard. While being supervised by Devore for her doctoral research, her committee member Edward Wilson had recently published *The Insect Societies* (1971) and was working on *Sociobiology: The New Synthesis* (1975), and her other committee member, Robert Trivers, was working on his papers pertaining to altruism (1971), parent-offspring conflict 1974 and parental investment theory 1972 (see also Sridhar 2016). Hrdy received her doctoral degree from Harvard, followed by a stint as a lecturer at Harvard, more fieldwork, a visiting professorship at Rice University near Baylor where her husband Dan was doing his medical residency, followed by time as a volunteer assistant at her children's daycare center back in Cambridge while Dan completed

his MD-PhD program at Harvard and MIT. In 1984, she and her husband both accepted jobs at the University of California at Davis, where she is now Professor Emerita.

Hrdy reports that this era was challenging in that it became marked by “science wars” against sociobiology. Her own work on infanticide as a reproductive strategy became controversial (see Rees 2009), and her publication in *American Scientist* (1977) resulted in letters to the editor and follow-up articles.

Her initial research on infanticide as a male reproductive strategy paralleled significant developments and paradigm changes in evolutionary biology, anthropology, and psychology, where these fields became influenced by models around the selfish gene and individual fitness. After her work on langurs, she widened her research focus to include topics that were previously understudied, including female intrasexual competition, female sexuality, alloparenting, and infant sharing.

Hrdy is a former Guggenheim fellow, member of the National Academy of Sciences, a fellow in the American Academy of Arts and Sciences, the California Academy of Sciences, Animal Behavior Society, and the American Philosophical Society. She was listed among the “50 Most Important Women in Science” by Discovery Magazine in 2001. In 2013, she received the Lifetime Achievement Award from the Human Behavior and Evolution Society, and in 2014, received the National Academy of Sciences Award for Scientific Reviewing. In addition to being Professor Emerita at the University of California-Davis, she is an Associate in the Peabody Museum of Archeology and Ethnology at Harvard. She and her husband have three children and combine growing walnuts with habitat restoration on their farm in Northern California (<http://www.citrona.com>).

Infanticide

In *The Langurs of Abu: Female and Male Strategies of Reproduction* (1977; paperback edition 1980), Hrdy chronicles five years of research. The work that she published on Hanuman langurs

provided a foundation for a shift in how the scientific community came to view infanticide in primates (including humans) but also female and male mating strategies more generally.

Originally, Hrdy undertook the study of langurs with the hypothesis that high population density among those living in Mount Abu, India, caused males to commit infanticide as a maladaptive behavior. However, she noted that males who are likely to be the fathers of infants born in their group are quite tolerant of infants. Further, overcrowding did not influence whether langur males committed infanticide or not. Instead, she discovered infants were only being attacked when males entered from outside the breeding system. The only plausible explanation was Darwin’s theory of sexual selection, and in particular, male intrasexual competition for access to mates.

Langur troops typically consist of one male and several females, with additional males who remain external to the core group. One of these outside males ousts the troop leader approximately every 2 years and, in the process, takes over the harem and often kills young infants. She documented that only un-weaned infants were attacked and proposed that by eliminating the source of lactational suppression of ovulation, the new leader could compress the mother’s fertility into the period he was likely to have reproductive access to her before another male replaced him. In other words, in killing the infants, the new leader increases the sexual receptivity of the females which results in a higher probability of him siring offspring with those females.

The arguments put forth by Hrdy were groundbreaking, as she posited that infanticidal behavior by male langurs was an adaptive reproductive strategy. Her research went one step further though, as she proposed that males relied on the mothers, not the infants, when deciding whether to attack or tolerate an infant, in that it depended on whether he had previously mated with the mother. In the paperback version of *The Langurs of Abu*, Hrdy cites evidence of infanticide as a heritable trait among rodents, and then almost two decades later, DNA analyses support that langur males only attack infants that are genetically unrelated (Borries et al. 1999).

The controversy that emerged in response to her arguments on the adaptive nature of infanticide lead her to complete an edited volume (Hausfater and Hrdy 1984, republished in 2008) entitled *Infanticide: Comparative and Evolutionary Perspectives*.

The Woman That Never Evolved

After studying langur monkeys, Hrdy began to consider sources of variation in female reproductive success. She had documented that the females mated with the new troop leader, but also with the old leader, and with males who were peripheral to the core group, even when they were already pregnant. She argued that females' promiscuity was an effective strategy to decrease the probability of their infant becoming a victim to infanticide by a male, given that he would likely not kill a related infant. In other words, females had evolved counterstrategies that were effective in working around males' strategies, including opportunistic promiscuity, which had previously been unexplored in the literature. Her interest in female primates, including women, and issues such as variation in their mating strategies and reproductive success, led to the publication of *The Woman That Never Evolved* (1981, revised paperback 1999). It was selected by the *New York Times* as a notable book for 1981.

At this point in her research, she began to argue that females were not coy or passive in the manner described by Darwin, as well as by others. She writes that "a handful of partially true assumptions were permitted to shape the construction of general evolutionary theories about sexual selection" (1986, p. 119). She questioned assumptions such as how sexual selection theory had been used to explain females' choosiness about mates (while males were argued to be indiscriminating), which led to views of males providing little, if any, parental support to offspring, females as having minimal reproductive variance relative to high variance among males, and females engaging in mating only for reproductive purposes.

In his conceptualization of sexual selection, Darwin (1871) had written that females are

relatively passive in the mating process but show some activity by selecting the best mate from an array of contenders. These narrow views of females remained over time and were strongly reinforced by the work of Angus Bateman (1948), leading to the dominant way of perceiving female and male sexuality. He had published work on fruit flies (*Drosophila melanogaster*), where he had altered some individuals and then determined how many offspring displayed each individual's genetic trademarks. His results (based entirely on looking at phenotypes, not behavior) showed more males than females did not have offspring, while some males had far more offspring than any female. He extrapolated these findings to suggest males had higher reproductive variance than females, but also that males are ardent and sexually indiscriminating, whereas females are sexually restrictive and coy. This view largely remains today in evolutionary psychology, despite repeated calls for it to be re-examined (e.g., Fisher and Burch, [in press](#)).

In *The Woman That Never Evolved*, Hrdy elaborated on female mating strategies in primates, including women. She argued that females are not passive, but instead are able to manipulate male reproductive strategies while simultaneously competing and cooperating with other females in areas that are relevant to them. She suggested that the reason women's competition has been largely neglected is because researchers have not developed the ability to adequately document it due to its subtle and covert nature. Her work clearly indicated that primate females were active strategists, seeking to increase their fitness using a variety of tactics. Female competition, Hrdy proposed, was key in shaping relationships among females, and used to respond to challenges in the local environment, including social context. Her work largely inspired the tremendous growth of research on female competition, resulting in compendiums such as Fisher (2017).

Further, at this point, males were considered essentially polygynous while females were thought to be monandrous. Her own research, supplemented with re-examination of the primate literature, caused her to realize that polyandrous

mating was common across primates. Therefore, not only was the ardent male-coy female perspective flawed, but so too were the underlying theories regarding mating systems.

On Mothering

After the work summarized in *The Woman That Never Evolved*, Hrdy continued to explore mothering in two books. The first of these, *Mother Nature: A History of Mothers, Infants and Natural Selection*, was published in 1999 and awarded the 2000 Howells Prize, among other considerations. It was also selected as one of the best books of 1999 by Publisher's Weekly and Library Journal. In this body of work, Hrdy departs from primarily focusing on nonhuman primates to begin to explore modern humans. However, she continued to rely on comparative work of nonhuman primates to inform her arguments.

Hrdy outlined how selective forces have shaped maternal behaviors and strategies, and in particular, how they involve trade-offs. She continued to challenge the long-held assumptions that pervade modern theorizing that are already noted (i.e., higher variance in reproductive success among males, males but not females are active in mating and compete to gain access to mates, females mating only as much as is needed to conceive offspring). The result of this limited view is that maternal success is seen as automatic, with little variance in mothering abilities or interest. Instead, she contended, mothering for humans means deciding whether one has the social support to raise infants and children before committing to having children. If the support is absent or weak, women may decide to abandon or kill their offspring. This decision is at least partially based on a mother without support realizing that she needs to reduce her current costs of caring for her young, in the hopes of being able to have future children with stronger support, and hence, better fitness.

Struggling to reconcile maternal love with ambivalence, Hrdy was struck by just how much help human mothers need, increasingly convinced that unlike other apes, mothers in

the line leading to the genus *Homo* must have evolved as cooperative breeders. "It's time then to ask," she wrote in *Mother Nature* "just who beside mothers subsidized the long, slow development that is the hallmark of the human species, the very late maturation that distinguishes us from every other primate?" (p. 265). Hunter-gatherers have short inter-birth intervals, with an average 2–3 years between children compared to six for other great apes. This interval produces overlapping nutritionally dependent altricial young. It means that mothers need to provide care for dependent young (e.g., toddlers) and infants while possibly being pregnant with the next child. This reproductive pattern is only possible if mothers receive assistance from others; their children would fare better, and the mother herself would be healthier. In this way, she drew a parallel reliance on allomaternal care in langurs and in humans which in both cases allowed mothers to breed faster after shorter intervals and still raise surviving offspring. Hrdy also discussed partible paternity, similar to polyandry, which exists among some cultures such that mothers have multiple mates to help provide and protect her children in the event that her primary mate deserts her or dies. In *Mothers and Others: The Evolutionary Origins of Mutual Understanding* (2009), she explored the implications of having to rely on alloparental care and provisioning of immatures for mothers and especially on infants.

Throughout these books, Hrdy highlights women as strategists, actively seeking to improve their individual and inclusive fitness. Consequences of striving to improve one's fitness can include child abandonment, neglect, and infanticide, where especially young women facing a less than desirable future may kill their offspring to increase their prospects. Further, infants who are likely to decrease the fitness of their siblings are often the victims; infants who are weak, display a disability, the wrong sex, or born too soon after the last child are typically victims. Collectively, Hrdy's research clearly indicates that the popular and common idea of a "maternal instinct" is simply flawed, given that mothers must remain evolved strategists.

On the Importance of Others

Hrdy's second book pertaining to mothering was *Mothers and Others: The Evolutionary Origins of Mutual Understanding* (2009). It was awarded the 2012 J. I. Staley Prize from the School for Advanced Research, which is awarded to a living author for a book that "exemplifies outstanding scholarship and writing in anthropology, but also goes beyond the discipline's traditional frontiers" (2020). It was also awarded the 2012 Howells Prize, given by the biological anthropology section of the American Anthropological Association, for informing "a wider audience of the significance of physical or biological anthropology in the social and biological sciences, and demonstrate a biocultural perspective" (2020).

At the end of working on *Mother Nature*, Hrdy realized that the traits associated with the life history of humans meant that our evolutionary history involved cooperative breeding (Johnson 2012). Human young are extremely dependent, and until the age of 18–20, they do not generate as many calories as they consume (Johnson 2012). Compared to other great apes, humans have the largest neonates, and their infants are costly in terms of requiring nutrition and protection, and overall, human children are the latest to mature. Alloparents (i.e., individuals other than parents) provide care and help by providing provisions for infants and children. These individuals include an impressive array of individuals: grandmothers, post-reproductive females, fathers and men who may be fathers, patrilineal relatives, matrilineal relatives, older siblings, aunts, uncles, and unrelated individuals in the group who help rear offspring in exchange for group membership. Further, Hrdy contended that mothers accept this help from others in an opportunistic fashion, based on the benefits such assistance brings to her and her children.

One point worth emphasizing is how Hrdy views children as active in helping to maintain their own survival and are not simply immature adults (a line of thought that helped to propel evolutionary developmental psychology forward as a sub-discipline). Humans rely extensively on wide social networks to successfully raise infants

and children. Humans, unlike other great apes, care for and pay attention to each others' children and engage in food sharing and share other scarce resources. Natural selection has thus favored the survival of children who are more easily monitored and receptive to being cared for by individuals other than the mother. Children who are able to engage socially with other individuals solicit their help and positive attention, determining whether someone may help or hurt them, and have a distinct advantage over those who are not able to do so. The importance of children as being able to solicit help from others must be noted, given that among hunter-gatherer societies (from which we may model our evolutionary heritage), infant mortality is approximately 50% (Volk and Atkinson 2013).

The ability of infants and children to engage with people other than their biological mother has led to several critical developments for humans, and indeed, it is these uniquely human adaptations that are truly astounding. Hrdy argued that these adaptations include our unique (compared to other great apes) ability to care about others and their intentions, anticipate other's needs, use empathy and have a theory of mind, to use language and gestures, and be able to coordinate action toward a common goal. Indeed, cooperation is a key feature to highlight; humans frequently help each other, including unrelated others, and anticipate their needs. However, it also involves complexity, in terms of worrying about other's views of us, or attempting to maintaining status, (see Pridmore-Brown 2009). Hrdy proposed that women's tendency toward tend-and-befriend (Taylor et al. 2000) to help create alloparents would have led to higher infant survival, and that those individuals with better skills for cooperating may have had better fitness.

Hrdy has researched a multitude of other related issues, which collectively serve to further the point that mothers are strategic, and that the relative contributions of people other than the biological mother can be critical for a cooperative breeding species such as humans. Individuals such as the maternal grandmother had long been overlooked, yet it is this relative who particularly improved infant survival, by providing food,

resources, and childcare. Fathers, too, play a role, albeit a much more conditional one, depending on issues such as paternity certainty, but also cultural context and individual variation.

Conclusions

Hrdy is an influential scholar who has shaped how we view topics such as strategies to promote inclusive fitness, parenting behavior, maternal love, competition, infanticide, the importance of non-related individuals in raising children, cooperation, and mating strategies. Ultimately, her work serves as a strong reminder that it is important to question past assumptions, and consider individuals as actively strategizing to increasing their fitness.

Dr. Sarah Brosnan is a researcher investigating the ontogeny of reciprocity and cooperation in primates. To date, she is best known for her work showing that primates detect and react to unequal pay for the same tasks (Brosnan and de Waal 2003).

Introduction

Dr. Sarah Brosnan researches mechanisms underlying cooperation, reciprocity, inequity, and other economic decision-making strategies from an

evolutionary perspective. She uses both human participants and nonhuman subjects in her investigation of the decisions individuals make and how they make them, how their social or ecological environments affect their decisions and interactions, and under what circumstances they alter their behaviors in line with these conditions (Brosnan 2014). Sarah Brosnan received her B.A. in Biology from Baylor University and went on to work with Dr. Frans de Waal at Emory University to complete her Ph.D. in their *Population, Biology, Ecology, and Evolution* program. Her research focuses on the evolution of economic decision-making strategies, with a particular focus on animal perceptions of the value of exchanged goods and services (Brosnan 2014).

Monkeys React to Unequal Pay

In 2003, Sarah Brosnan and Frans de Waal published a study showing that monkeys detect and react to unequal pay, which was previously believed to be an exclusively human trait. In the study, five capuchin female monkeys were trained to exchange tokens with a human researcher to receive food rewards. Each subject then experienced each of four conditions: (1) “equality,” in which two monkeys exchanged for a cucumber reward; (2) “inequality,” in which the test monkey exchanged for a cucumber while its partner exchanged for a grape (a higher quality food); (3) “effort control” in which a grape was simply handed to the partner without exchanging a token and then the subject herself exchanged a token for a cucumber; and (4) “food controls” in which the partner was absent, yet the subject witnessed a grape being placed in the location where the partner normally sat, followed by the subject herself exchanging for a cucumber. Researchers measured the female subject’s latency to successfully exchange the token for the food reward, and assessed situations in which she did not exchange the token, or refused the given reward. It was found that subjects were less likely to exchange for low-value rewards (i.e., cucumber) when high-value rewards were present, and even less likely to exchange if the partner received the high-value

reward with no effort. Because refusals were more likely when the partner was present, Brosnan and de Waal concluded that capuchins must be assessing the value of their reward by comparing them to visible conspecifics. Results shed light on the evolution of adaptations for group living, such as cooperation, fairness, and value estimation (Brosnan and de Waal 2003).

This study provided the first evidence that, like humans, capuchin monkeys comparatively estimate the value of rewards, evaluating both availability and effort compared to others. Furthermore, these monkeys display an emotional response to unfairness, such as throwing away lower-value rewards after seeing a partner receive a higher-value reward for the same or relatively little effort. These reactions are integral to long-term human cooperation and influence how we form expectations about resource value, work effort, and ethical treatment of others and how resources should be divided (Brosnan and de Waal 2003).

Conclusion

Dr. Brosnan continues to research primate cognition, including the evolution of cooperation, fairness, property, prosocial behavior, comparative economics, social learning, and social and ecological influences on decision-making. She is currently an associate professor of psychology at Georgia State University (GSU) in Atlanta, GA (USA). She is a research associate in GSU's Neuroscience Institute and is also a member of the *Brains and Behavior* program and the *Center for Behavioral Neuroscience*. Savanna Hypothesis and Landscape Preferences, The

Kevin Bennett

Definition

According to the savanna hypothesis (Orians 1980, 1986), current habitat biases were shaped by selection pressures in our ancestral past. The theory argues that natural selection favored preferences, motivations, and decision rules that

attract us to resource rich environments over resource poor environments.

Introduction

Current habitat preferences were shaped by selection pressures in our ancestral past, according to the *savanna hypothesis* (Orians 1980). The theory argues that selection favored preferences, motivations, and decision rules that attract us to resource rich environments while avoiding environments populated with survival threats and lacking resources. The African savanna, widely believed to be the site in which humans originated, fulfills these requirements.

Two perspectives are helpful in addressing evolved responses to landscapes, one spatial and the other temporal. The spatial frame of reference points out particular stages of exploration in novel landscapes. The temporal dimension concerns short-term and long-term habitat variation in critical survival factors (e.g., weather patterns and seasonal transitions).

Stages of Exploration

The details of the savanna hypothesis can be unfolded to include three stages of habitat selection: *selection*, *information gathering*, and *exploitation* (Orians and Heerwagen 1992). The primary decision faced in stage 1 is whether to canvass or flee a landscape upon initial encounter. Completely closed forest canopies are rejected because they inhibit viewing and mobility. Wide-open environments lacking cover and protection are also abandoned. Initial preferences and choices made during the selection stage are often emotional rather than intellectual. They do not usually involve an exhaustive cognitive evaluation of all the benefits and disadvantages of the landscape. It is something closer to sensing a vibe or having a hunch.

Assuming the experience in first stage is decent, individuals begin exploring the environment for resources and possible hazards. Stage 2, *information gathering*, involves mentally mapping the area for hidden places to harbor oneself,

family, and allies. One can also evaluate possible routes for escape in the event of danger. At this stage, people show a preference for hills and pathways that change elevation and wind around, hinting at the potential of something promising around the corner. One study found that people have an affection for mystery and intrigue at this stage (Kaplan 1992). In sum, great effort is put into risk assessment and resource estimation at this stage.

The decision of whether to stay or leave is at the heart of stage 3, *exploitation*. This final stage involves elaborate mental calculations that help to determine if one should stay long enough to enjoy the full bounty of resources available in the habitat. All humans face decisions about how much time and energy to allocate to competing demands. The solutions to these decisions involve trade-offs. A lofty rock ridge brings benefits (e.g., easy observation of competitors below), but they may not outweigh the risk of death that comes from falling. Likewise, a clear and exposed area good for foraging may open the door to predators (Orians and Heerwagen 1992).

Weather Patterns and Seasonal Transitions

An additional layer of the savanna hypothesis involves decision-making over different time frames (Orians and Heerwagen 1992). Light availability and weather patterns are two time-related factors that impact choices. Long shadows at the end of the day may elicit the desire to set up campsite instead of continuing to move through the environment in darkness. Likewise, daily weather issues can force one to seek shelter quickly. Dark clouds, winds, thunder, and lightning are cues that may initiate the decision-making process.

Along with daily fluctuations, humans are sensitive to environmental changes on a seasonal scale. In general, natural selection favors traits that maximize benefits and minimize costs. People will show preferences for long-term signs of robust prosperity because the algorithms that make habitat-related decisions were shaped

over time in response to specific positive and negative features of the environment. Indicators of harvest, such as fruit, budding flowers, and verdure, are favored over bare trees and impoverished fields.

Landscape Preferences

Support for the savanna hypothesis can be found in studies of landscape preferences. One such study asked subjects to rate a series of standardized photographs of trees taken in Kenya. Pictures were taken under similar daylight and weather conditions. Each photo focused on a single tree and varied along four dimensions – canopy shape, canopy density, trunk height, and branching pattern. Subjects from Australia, Argentina, and the United States all showed similar taste in the photos depicting trees. The trees that made a moderately dense canopy with trunks that separated in two near the ground – the savanna-like trees – were preferred by participants across the three cultures (Orians and Heerwagen 1992).

Modern technology, structural designs, and construction materials allow us to comfortably inhabit climates that would have required intense effort just a few generations ago. Still, we carry with us the psychological preferences shaped by generations of ancestors living in a much different world and often customize our environments to resemble that ancient habitat. Most of us prefer physical spaces that offer views of green vistas over windowless basements. Looking at trees might even have a tangible health benefit: Patients who viewed trees outside the window recovered more quickly from hospital stays (Ulrich 1984). Flowers also appear to have a positive impact on hospital patients. Bringing flowers increases optimism and actually improves the rate of recovery (Watson and Burlingame 1960).

The relationship between stress and uncultivated outdoor settings may play a role in this. When placed in uncertain and stressful situations, individuals who viewed pictures of nature scenery showed less physiological distress (Ulrich 1986). Contact with vegetation need not be active, such as gardening, to provide health benefits. Passively viewing

vegetation through a window can produce desirable effects as well. Studies in biophilic design demonstrate that people living and working in spaces with vegetation compared to those without vegetation show improved performance on mental tasks, more positive moods, greater ability to refocus attention, stress reduction, and diminished perceptions of pain in health-care settings (Kellert et al. 2008).

Additional support for the savanna hypothesis comes from the body of evidence showing that humans often prefer natural environments over built environments (Kaplan and Kaplan 1982). Using data from 30 studies, Kaplan (1992) summarized the results of participant ratings of photographed scenes of Western Australia, Egypt, Korea, British Columbia, and the United States. Across these varied geographic regions, participants preferred natural environments over built environments. Other data suggest that the addition of trees and vegetation increases positive evaluations of built environments, thus demonstrating the transformative power of foliage (Ulrich 1983).

One of the earliest studies to test the idea that people have a generalized bias toward savanna-like environments hypothesized that “innate predispositions” for the savanna should be more likely to be revealed in children than in adults, given that adults have had greater opportunity to experience non-savanna ecosystems (Balling and Falk 1982). In a study that included six age groups (8, 11, 15, 18, 35, and 70 or over), subjects were asked to rate photos from five natural biomes on scales that measured how much they would like to “live in” and “visit” each one. The researchers found that the youngest group (8-year-old children) preferred the savanna over the other habitats on both scales. The deciduous forest, coniferous forest, and savanna were equally liked among ages 15–70, with ratings for the desert and rainforest coming in lower at all ages. The study also implies that people have an aversion to drought conditions and arid landscapes. Photos depicting greener savanna were rated higher than similar savanna photos taken during the dry season. Finally, all age groups gave the lowest ratings to the desert environment (Balling and Falk 1982).

Conclusion

In a broad sense, the savanna hypothesis addresses the issue of how we select places to live and why we find some landscapes more beautiful than others. The central argument is that our preferences in this domain were shaped over evolutionary time *through the repeated selection of safe and healthy environments over dangerous and resource poor landscapes*.

Definition

The Savanna Hypothesis states that we retain genetically based preferences for features of high-quality African savannas where our ancestors lived when their brains and bodies evolved into their modern forms.

Introduction

Selection of a place to live is a crucial step in the lives of most animals. Selection depends on the recognition of objects, sounds, and odors to which an animal, molded by natural selection, responds *as if* it understood their significance for its future survival and reproductive success. Evolutionary theory suggests that the ability of a landscape to evoke positive emotional states should be positively correlated with the expected survival and reproductive success of individuals of that species in it. In other words, good habitats should evoke strong positive responses; poor habitats should evoke weak or negative responses (Orians and Heerwagen 1992). Habitat selection has served as a conceptual basis for many studies on human responses to landscape features (Orians 1980;

Heerwagen and Orians 1993, see Orians 2014 for a synthesis).

Rarely did habitats occupied by humans during most of our evolutionary history provide reliable resources long enough to enable our ancestors to settle in permanent sites. Frequent moves through the landscape were the rule even though traditional sites might be revisited on an annual basis (Campbell 1985). We have lived in mechanized and urban environments for relatively few generations. Unless there has been strong counter-selection against them, not enough time has elapsed for our evolutionarily based response patterns to landscapes to have been substantially modified in the dramatically new and different environments in which we live today.

People's initial emotional responses to an unfamiliar environment are almost instantaneous and noncognitive. The strength of these emotional responses strongly influences immediate decisions about where to stop and explore. Although no direct evidence yet exists for genetic influences on these responses, a number of investigators have used an evolutionary perspective to generate testable predictions about human responses to environmental features. Among the hypotheses, they have generated is the **savanna hypothesis** (Orians 1980).

The Savanna Hypothesis

The savanna hypothesis is based on a large body of evidence showing that our ancestors lived in African savannas during the time when our brains tripled in size and we became human. Tropical savannas are characterized by relatively low and highly seasonal rainfall. They have widely spaced trees interspersed with areas of treeless grassland. The open canopy allows sufficient light to reach the ground to support a vibrant herbaceous layer consisting primarily of grasses. In some regions, especially Africa, the scattered trees and rich herbaceous understory support large populations of grazing and browsing herbivores and their predators. In tropical savannas, most resource production takes place within a few meters of the ground where people and grazing and browsing mammals

can easily harvest it. Meat production is higher in savannas than in forests, where much primary production goes to wood, and in deserts, where overall productivity is low. In addition, many savanna plants have underground storage organs that a person can harvest with a simple digging stick.

During their long occupancy of African savannas, our ancestors lived in small social groups; many members were close genetic relatives. They had few material possessions that they carried with them as they moved their seasonal campsites to follow changes in food and water availability. Bipedal locomotion, which reduced both heat stress and water loss, and loss of body hair, enabled our ancestors to travel great distances across savanna landscapes in search of carcasses at times of day when competing and dangerous carnivores would have been resting in the shade.

We have strong reasons to expect that contemporary human behavior should reflect adaptations of our ancestors to African savannas. A relatively small number of generations separate us from our ancestral "mother-Eve," who lived some five million years ago in East Africa. Evidence from a number of species demonstrates that behavioral patterns may persist long after selection continued to influence them (Coss and Goldthwaite 1995). Even though traits can persist for many generations in the absence of selection against them, some human traits, such as evolved responses to the chemical characteristics of the foods that people encountered as they occupied new geographical regions (Nabhan 2004), have evolved relatively rapidly during recent millennia.

The savanna hypothesis has generated a variety of predictions about how people may respond today to the environment. At a large scale, people respond to features of the broad landscape, that is, scattered trees with an herbaceous understory and signs of water. They also respond to the shapes of the trees that dominate the highest quality savannas. At a still smaller scale, because most savanna trees and shrubs have either small simple leaves or highly divided compound leaves with small leaflets, such leaves should also be attractive to us today.

When our ancestors descended from the trees and become primarily terrestrial, they increasingly added animal flesh to their diets. Evidence of the presence of medium-sized and large animals should enhance the attractiveness of a landscape. In addition, perhaps by sampling animals killed by savanna fires, our ancestors discovered that cooked meat was tasty as well as being much easier to chew, swallow, and digest. They also discovered that many inedible raw things were good to eat when cooked. Cooking greatly expanded the range of things they could eat; it outsourced to fire a major part of the cost of digestion. Energy previously expended in chewing food and breaking down complex molecules to more easily digested smaller ones was available for other functions, most notably for supporting an energy-demanding larger brain. Major morphological changes among our ancestors – reduction in the length of the digestive tract, reduction in the mass of the jaws – were probably made possible by cooking (Wrangham 2009).

Humans are not desert-adapted animals. Our ancestors would have needed to drink every day; dehydration was probably a constant risk. Their home ranges were probably determined by the greatly restricted distribution of water during the dry season and location of safe sleeping sites. Although water is present in all environments in which humans can survive, evidence of the presence of this vital and scarce resource in savannas should have a special appeal for us today.

Landscape Features

Predictions about which landscape features are most attractive to people today have been tested by observing people's responses to photographs and paintings of landscapes and by studying the features of "aesthetic environments," that is, environments, such as parks and gardens, that are designed to be places in which people would like to spend time (Orians 1980, 2014). These experiments are appropriate because people respond similarly to photographs and real settings (Shuttleworth 1980).

Responses to paintings and photographs of landscapes. Landscapes first appeared in paintings as background to other actions and events, usually religious. Only later did they become the direct subjects of paintings. Psychologists have tested predictions about landscape preferences by asking participants to evaluate paintings and photographs of landscapes that differ in structure, composition, social information, number and kinds of objects, and colors. Two artists, Vitaly Komar and Alexander Melamid (1997), asked a marketing research firm to conduct a survey to assess the attitudes and preferences of adult Americans about landscapes. Pollsters asked people about their favorite color and the criteria they would use to select pictures, photographs, or other pieces of art for their homes; whether they preferred natural or portrait settings, indoor or outdoor scenes, geometric or random patterns, flat or richly texture surfaces, and sharp angles or soft curves.

Komar and Melamid incorporated the most preferred features into a single landscape painting, *America's Most Wanted*. The savanna-like landscape features a lake, gently sloping hills in the background, and a wooded cliff. The most prominent trees would be easy to climb in the event of sudden danger. The scene features two deer, three young people in their reproductive prime plus an older man. Komar and Melamid got similar results from comparative surveys in nine other countries. All people preferred savannas with water, easily climbed trees, happy people, and large mammals. Overwhelmingly they also preferred painted outdoor scenes that looked "real."

The kinds of changes landscape architects have recommended to their prospective customers have also been used to test predictions from the savanna hypothesis. Humphrey Repton, an eighteenth century British landscape architect, drew "before" and "after" pictures of the landscapes he proposed to modify and bound them in red covers together with prose that explained why he suggested those changes (Repton 1907). Based on the savanna hypothesis, Heerwagen and Orians (1993) correctly predicted that Repton would propose changes that created more savanna-like scenes,

increased visual access, fragmented closed woods, opened up distant views to the horizon, added refuges and cues that signaled ease of movement, and added evidence of resource availability, particularly large mammals.

Parks and Gardens. People probably designed gardens long before they invented agriculture, but prior to the Medieval Period we know little about the forms of ancient gardens. Medieval gardens were either herb gardens designed for growing food plants or places set aside for recreation. Which species of plants were available, what societal ideals and symbols plants or structures represented, and societal attitudes towards nature, influenced the forms of gardens and parks (Tuan 1974). Nonetheless, habitat preferences that evolved while our ancestors lived in African savannas should continue to influence how we design parks and gardens.

If our aesthetic preferences today reflect our savanna origins, parks and gardens should be designed to be more similar to African savanna vegetation than to either closed forests or deserts. Trees similar to those that dominate resource-rich savannas should be preferentially planted. Japanese gardens are savanna-like in that trees are scattered and are pruned or genetically modified to resemble savanna trees. Water is emphasized, in the form of ponds or as rocks and gravel molded to simulate waves (Orians 2014).

Western gardening began in the Middle East, a dry region with brutally hot summers. Persian gardens were designed as places to sit and escape from the sun's heat. They were models for Islamic gardens, which spread east to India and west to Turkey, North Africa, and Spain. We have only indirect evidence of the forms of those ancient Persian gardens. One source is carpets. Gardens portrayed on surviving Persian carpets have a small border of flowers, followed by a wider one of trees. The main part of the garden is divided into four sections, separated by rivers with fish. Each of the four sections is divided into six squares where flowerbeds alternate with beds containing plane and cypress trees. Marco Polo's descriptions of gardens he observed during the 1260s accord with those patterns. No ancient Persian gardens remain

today, but the Moorish gardens of southern Spain retain some of those features.

Political stability in eighteenth century England, combined with great wealth of the upper classes, favored expansive landscape gardens. The most famous ones, designed by Lancelot Brown (1716–1783), closely resembled tropical savannas in having scattered trees, often in clumps. Unlike in Japanese gardens, trees in English gardens were not pruned; only much more recently were mutants with different shapes incorporated into them.

British geographer Jay Appleton (1975) developed prospect/refuge theory to predict which features of a landscape increase the likelihood that the individual will find a scene attractive or unattractive. Appleton proposed that *prospect* should be attractive because it offered a good view or vista from which an individual could learn valuable things about the area. *Refuge* should enhance a scene by providing cover from which to observe and assess the environment. The presence of *hazards*, risks an individual would face while exploring an environment, should make an environment less attractive (see Orians 2014 for details).

In combination, the savanna hypothesis and prospect-refuge theory predict that garden designers should provide visitors with a succession of refuges, each one offering a view (prospect) of a different part of the garden. Views should feature areas that have water, appear resource-rich, and offer safe walking routes. Aesthetic experiences would be enhanced if walkers followed a specific route of travel indicated by clearly marked paths.

Japanese gardens fit these predictions. Paths curve; rocks, trees, or shrubs frequently hide their courses. A walker emerges from one refuge with a new prospect view. After a short walk through an open area, another refuge (a group of trees and shrubs that obscures other parts of the garden) is encountered. Multiple prospect views also foster an impression that a garden is much larger than it actually is.

The most famous of eighteenth century English gardens – Wickenham, Stowe, and Stourhead – were also designed with prescribed routes. Guidebooks informed walkers where to

go and how to interpret what they saw (Ross 1998). Controversy exists about which interpretations were really intended by the designers of the gardens, but visitors were expected to understand that the views, sculptures, and structures distributed around the gardens had classical, religious, or sexual significance. Whatever the interpretations, visitors experienced a sequence of prospect/refuge events. The most elaborate formal garden designed around a specified route of travel is the largest – Versailles. Louis XIV wrote an itinerary for viewing Versailles that prescribed the route and commanded visitors to look at views in a specific way. A visitor that followed Louis' itinerary moved through the garden from one fountain to another, never losing sight of water, as long as helpers raced along hidden parallel passages to turn on and off fountains as needed.

Tree Shapes

Trees are dominant features of most environments historically used by people. They are sources of food, shade, and safety. The trees that dominate resource-rich tropical savannas are typically broader than they are tall, have canopies wider than they are deep, and have trunks that are short relative to their total height. In drier, less productive habitats, most trees are short; many have multiple trunks. Thus, tree growth forms signal the resource potential of the area.

Early gardeners should have preferred trees with shapes similar to species common in high-quality savannas. Subsequent modifications of those trees should have made them even more like trees of resource-rich savannas than their wild ancestors. These predictions have been tested in Japanese gardens where gardeners prune many woody plants to alter their shapes and have selected and used genetically modified types of woody plants. The three Japanese maple species that dominate gardens naturally grow sideways to seek patches of brighter light in the forest understory. Japanese gardeners do not need to prune them extensively; they already have savanna-like shapes (Orians 2014). Most rarely planted species

are taller relative to their breadth than the commonly planted ones.

The natural growth forms of conifers commonly planted in Japanese gardens are not savanna-like, but Japanese red pines that grow in windswept locations, such as seashores and mountain ridges, resemble tropical savanna trees. Their growth-form flexibility may have attracted Japanese gardeners. Red pines and other species of conifers in gardens are pruned so that they are broader than tall, have trunks that divide close to the ground, and have canopy layering similar to that of African savanna trees (Orians 2014).

Heerwagen and Orians (1993) recorded people's responses to photographs of *Acacia tortilis*, the species that dominates resource-rich East African savannas. They tested four hypotheses: (1) Trees whose trunks bifurcate closer to the ground should be more attractive than trees whose trunks divide higher up. (2) Trees with moderate canopy density should be more attractive than trees with low or high canopy density. (3) Trees with a high canopy layering should be more attractive than trees with low or moderate layering. (4) The broader a tree's canopy relative to its height, the more attractive it should be. As predicted, people on three continents preferred *Acacia tortilis* trees that had highly or moderately layered canopies, low-bifurcating trunks, and higher canopy width/tree height ratios than trees with narrow canopies and trunks that split higher above the ground. Contrary to predictions, the canopy width/canopy height ratio did not influence a tree's attractiveness.

College students in Australia, Brazil, Canada, Israel, Japan, and the United States all rated spreading and globular trees higher than conical and columnar ones (Sommer and Summit 1996). College students from Zimbabwe, South Africa, Estonia, Italy, Switzerland, and the US-Mexico border also preferred trees with an acacia-like shape (Sommer 1997). Participants also scored trees more highly if they were common where they had grown up, indicating that early exposure to tree shapes also increases their attractiveness. In laboratory experiments, people have lower blood pressure when they view pictures of trees with

spreading rather than rounded canopies (Lohr and Pearson-Mims 2006).

Most experiments have been conducted with adults. Children should respond differently to trees; their responses should change with age as their ability to climb improves. Coss and Moore (2002) tested whether young children with little or no tree-climbing experience understood that trees could be antipredator refuges and sources of shade by asking them where they would seek refuge from a predator. Because our female ancestors were better climbers than males during most of human evolution, Coss and Moore predicted that preschool girls would value trees as antipredator refuges more highly than preschool boys did. As predicted, girls selected the acacia tree more often than either a crevice or top of a boulder in an imaginary landscape. The boys, on the other hand, did not favor any one of the three.

Leaves

Because the dominant trees of high-quality African savannas have small compound leaves, the savanna hypothesis predicts that trees commonly planted in gardens should have smaller, more deeply divided leaves than rarely planted ones. As expected, the maples commonly planted in Japanese gardens have simple leaves, but they have from five to seven lobes that penetrate at least to the middle of the blade, giving them a compound-like appearance (Orians 2014). Maple cultivars commonly planted in gardens have leaves that are much smaller than those of wild individuals. The leaves of very few cultivars are as shallowly lobed as wild-type *Acer palmatum*. More than half are lobed to the base, rendering them compound.

Cliffs

A prime requirement of a suitable residence is protection from the dangers posed by the physical environment – wind, rain, and extreme temperatures – and from dangerous animals and other humans. The most important predators on our

ancestors and tropical people today hunt primarily at night. Humans probably were unable to sleep on the ground until they domesticated fire and learned how to build structures that predators could not penetrate. Simple protections, such as fire, thorn bushes, or animal bones, would have been sufficient to repel predators, but they would have offered little protection from hostile humans. A cliffside cave with difficult access and a fire at its entrance would have been effective against both. Early humans made extensive use of caves as living quarters; some of them were occupied for thousands of years.

Cliffs and bluffs attract us today, an attraction often associated with a strong desire to climb to the top. Climbing cliffs, which requires physical effort that is normally shunned, is intrinsically rewarding. It is engaged in enthusiastically by well-fed, unthreatened persons with no immediate intention of hunting or pursuing or escaping from hostile humans.

Water. In seasonally dry African savannas, our ancestors needed to drink every day. Dehydration would have been a constant risk. Their home ranges were probably determined by the distribution of dry-season water and safe sleeping sites. A legacy of that intimate relationship is that water is prominent in myths, such as flood myths, which are found throughout Africa, Australia, Eurasia, and the Americas (Witzel 2015).

Yet, water offers both positive and negative affordances. We need water for drinking, washing, and cooking. Aquatic environments have greater variety and density of foods than drier places, but many serious diseases are water-borne. Water may form barriers to movement (lakes and rivers) and pose hazards (cascades, rapids, and waves), particularly during stormy weather. Which of these features is most relevant varies with distance between the viewer and the water and a viewer's physiological needs.

Water nearly always enhances the quality of a scene (Ulrich 1981). People rank natural scenes containing water higher than scenes without water. Swedish college students ranked natural scenes with water higher than natural scenes without water on scales of ugly-beautiful and unpleasant-pleasant (Ulrich 1981). College students in North Carolina,

viewing colored slides depicting different types of waterscapes (waterfalls, rushing mountain streams, rivers, lakes, ponds, swampy areas), ranked swampy areas with stagnant, slime-covered water lower than other types of scenes (Herzog 1985). Water is prominent in most of Turner's "Picturesque Views in England and Wales." Most of them show people boating, fishing, hunting, watering livestock, or simply relaxing near water (Shanes 1979).

In the most definitive study of people's responses to water, investigators electronically manipulated photographs to delete features in otherwise identical pictures. Evidence that water was dirty or polluted, such as scum or detritus, greatly reduced the desirability of the scene for recreation (Wilson et al. 1995). People find scenes depicting water, or lush vegetation that grows near water, more attractive than strictly arid scenes (Balling and Falk 1982; Lyons 1983). Amplitudes of participants' EEG, which measures physiological arousal, were consistently higher when individuals viewed vegetation scenes rather than urban scenes. Amplitudes were lower when they viewed scenes with water than scenes without water (Ulrich 1981). Scenes with water evoked the strongest positive ratings as well as the greatest amount of "wakefully relaxed" cortical activity, measured as recordings of alpha wave amplitude (Ulrich 1981).

Children also prefer scenes with water (Zube et al. 1987; Bernáldez et al. 1987). They also find savanna pictures taken during the wet season, when grasses are green, more appealing than those taken during the dry season, when grasses are brown, even though no water is apparent (Lyons 1983). Desert scenes are the least attractive to children among an array of slides showing African savannas and relatively dense coniferous and deciduous North American forests (Balling and Falk 1982; Lyons 1983).

Our strong attraction to water also expresses itself in our choices of the surface finishes of art works and consumer products (Coss 2003). Bone artifacts older than 70,000 years of age in Blombos Cave, South Africa, were ground and polished to transform them into shining awls and symmetrical points (Henshilwood et al. 2001). The appeal of luster may have influenced choice

of materials for decorative objects, beginning with malleable copper for jewelry in the early Neolithic (Mellaart 1968), followed by gold and silver. Our attraction to gold, silver, and diamonds may be the result of our attraction to the glitter of water, a truly valuable substance.

Conclusion

The Savanna Hypothesis has proven highly successful in generating a variety of testable hypotheses that have extended, refined, and altered its original formulation and conceptual foundation. A rich and expanding literature shows that many of our immediate and unconscious responses to landscapes, in photos and paintings as well as real environments, accord with predictions generated by the hypothesis. We have stronger positive responses to the shapes of trees that dominate high-quality savannas, both as indicators of habitat quality and as providers of immediate benefits such as shade and safety. Water, which was scarce during the dry season in African savannas, enhances our appreciation of landscapes. The experiments conducted to date indicate that we have immediate and strong responses, both positive and negative, to landscapes, but that we are generally unable to explain our reactions. An evolutionary perspective suggests that we should expect responses that had to be made quickly, without time for reflection and evaluation, to be unconscious. Although the existing experimental evidence is highly suggestive, much more research is needed to determine which of these responses are truly universal and to assess how much our evolved responses to landscapes can be modified by the specific experiences individuals have as they grow up and experience a wide variety of environments.

Definition

A process in which more competent people provide a temporary framework that supports children's thinking at a higher level than children could manage on their own.

Introduction

Scaffolding is a method of teaching, where a more knowledgeable individual provides a framework that allows a less knowledgeable individual to be able to think at a higher level than they would have been able to on their own. The goal is for the less knowledgeable individual to eventually be able to think at that level or complete a specific task on their own. Giving this framework can include demonstrating how the task is done, explaining the overall goal, and helping with the most complex parts of the task. In general, this is how most parents teach their children throughout their lives, and this type of teaching has also been adopted into educational settings. Through scaffolding, the learner may start by requiring extensive help and then less and less support until they are able to complete the task on their own. It is vital for the more knowledgeable individual to instruct, model appropriately, and use questions to assist and to provide feedback (Sanders and Welk 2005).

Development of Scaffolding

Over the last century, the concept of scaffolding has been defined, strategized, and implemented both organically and purposefully into many learning environments. Historically, scaffolding derived from the work of tutors, whose main focus was to deliver information as well as content, to assist the learner in understanding a topic (Wood et al. 1976). Child development theorists, Albert Bandura and Lev Vygotsky, explored this process of learning through scaffolding using two different frameworks.

First, Bandura (1989), using social cognitive theories, believed that the environment was a crucial aspect in the way people learn, as we use attention, retention, repetition, and motivation to observe our surroundings, behaviors, and information in front of us. We observe learning in several types of environments: a classroom, at home, or on a playground. It is through the abovementioned learning processes that we pay particular attention to the information we observe and retain what we are interested in or what connects to us. Through repetition, the information moves from our working memory to our long-term memory, and finally, intrinsic and extrinsic motivation to succeed and achieve, allows us to push into more difficult learning scenarios (Bandura 1989).

On the other hand, Vygotsky theorized that our learning derives from exchanges we have with our own cultural groups and when we learn information, we need it to connect to our pre-existing knowledge and social experiences to make better sense of it (Vygotsky et al. 1980). Vygotsky believed that knowledge construction happens when the individual learner interacts with others around them. According to Vygotsky, the basis of learning is in interacting with other people with a focus on social interaction, the more knowledgeable other, and the zone of proximal development. The zone of proximal development is the difference between what a learner can do without help and what the learner can do with guidance from a more knowledgeable individual. Through guidance and collaboration, this is where students learn to build on

what they already know to achieve a higher level of understanding or further knowledge (Black and Allen 2018). This is where scaffolding comes in, as it is the process of teachers demonstrating how to solve a problem and then taking a step back and offering support when needed. In other words, the basis of higher-order learning is when a child or person interacts with someone who has more knowledge than him or her (Sanders and Welk 2005). The learner must master tasks in stages and expand on prior knowledge with each stage progression. This is often seen from early on in development, with children from a young age being shown how to complete basic tasks from their parents or caregivers.

Parental Scaffolding

Scaffolding is often the way in which parents teach their children from a very young age. Adults tend to model behavior, helping children with tasks a lot at first, assisting them less and less until they are able to complete the task on his or her own. Research has consistently found positive effects between parental scaffolding and the abilities of the child. For example, a study by Hammond and Cappendale (2015) found that parental scaffolding of children's participation in chores was significantly correlated with that child's willingness to help. It is therefore important to consider that the role of parents when it comes to scaffolding is not only for academic tasks (e.g., helping with homework) but also daily tasks and chores. With these social frameworks in mind, parents should consider the impact of modeling positive actions and instructing children step by step. Further, research has also found significant effects with parental scaffolding and improved executive functioning and problem-solving abilities of the child (Hammond et al. 2012). Parents who effectively used scaffolding tended to have children with improved problem-solving abilities. Moreover, a study by Neitzel and Stright (2003) concluded that parental scaffolding is the basis for the self-regulatory competence of the child and is associated with both problem-solving skills and

academic self-regulation. In other words, children were found to have improved self-regulatory abilities when their parents effectively used scaffolding when teaching them how to do things. Overall, research seems to support that parental scaffolding is not only important for tasks at home but can also impact the child's behavior in an academic setting.

Scaffolding in the Classroom

Scaffolding is an important skill for educators to utilize within a classroom setting. Mercer (2013) argues that the best strategies for scaffolding are through appropriation of information, co-construction of information, and transformation of an individual's reasoning or understanding. While these strategies are within the framework discussed, these newer strategies also tend to focus on the collaborative aspects of scaffolding, rather than the individual retention and delivery of knowledge (Mercer 2013). Further, Black and Allen (2018) explain that the best type of information to work with when scaffolding are real-life problems, as students need to be able to relate to the information. When students collaborate with information from real-world experiences or events, they are able to engage and apply that knowledge to different scenarios and the knowledge and skills can therefore become more transferable (Black and Allen 2018). The use of strong questioning can help the student move between zones of development (i.e., progressing from what they don't know to having said knowledge) as students begin to think about what they know, the perspective they want to take, and how to apply that knowledge to other problems or experiences (Black and Allen 2018). It is also important to randomly assign students to different groups to work together. If students are not placed in groups with differing perspectives, it is unlikely that the questions will challenge their pre-existing way of thinking and allow them to build from their prior knowledge to transform their learning, ultimately enhancing their ability to transfer higher-level information from one environment to another (Black and Allen 2018).

As scaffolding has moved from tutoring to being integrated into classrooms, teachers and researchers have developed several strategies as to best implement a scaffolded learning environment. Strategies for scaffolding range from the process of implementation to the specific content, to reflection, and to questioning afterwards. According to Wood et al. (1976), there are six keys strategies to effective scaffolding:

- (1) Recruit interest in and adherence to requirements of the task.
- (2) Simplify the task by reducing the number of actions.
- (3) Maintain direction by motivating the learner to stay on task.
- (4) Mark critical features by accentuating the most important parts.
- (5) Control frustration while keeping the learning responsible for the task.
- (6) Demonstrate or model solutions.

(Wood et al. 1976 as cited in Black and Allen 2018, p. 82).

Limitations of Scaffolding and Recommendations to Use It Effectively

It is important to consider that while scaffolding can have many positive effects to children, the results of scaffolding in an educational setting are only as good as the delivery of the model. For as many scaffolding strategies as there are, there are equally as many drawbacks to the process ranging from interactions with groups to the delivery of the scaffolding process. First, collaboration and group work are skills that need to be taught, as most students do not have the natural ability to effectively communicate ideas to reach a higher level of learning or to push through the next circle of the zone of proximal development (Black and Allen 2018). Mercer (2013) argues that argumentation is a key skill in collaborative scaffolding, and if students are not taught to critically discuss perspectives and opinions, they will not develop the transformative process necessary for true scaffolding to occur. Next, adults choosing to use

scaffolding should be aware that placing students in homogeneous groups to collaborate is not necessarily the most effective, as students tend to share similar perspectives and experiences; they likely will not formulate higher-order ideas or be challenged by multiple perspectives (Black and Allen 2018). Lastly, modeling is a large component of successful scaffolding. If modeling is rushed or not personalized by being simplified for each learner, students will likely not reach their potential for expanding their knowledge and building the transferable skills necessary for successful collaboration and application of their learning in multiple contexts (Black and Allen 2018).

Conclusion

Overall, scaffolding is an important concept for individuals working with children and youth to foster and utilize. From a young age, scaffolding can have positive effects on child development, particularly as children learn about the world around them and how to complete tasks in everyday life. Educationally, it is important that educators are effectively executing scaffolding in classroom settings, as Fischer (2018) explains that when students are learning through scaffolding, there is a natural phasing out of direction given by the teacher. However, if the students have not successfully been challenged to think more critically and advance their knowledge base, the likelihood that the students will be able to successfully transition the information and skills outside of the individual scenario is limited. Children naturally learn through social interactions around them, and therefore it is important to ensure that these interactions are positive and helpful in the learning of the child.

Introduction

A subsection of body modification that signifies complex costly signaling is scarification. Today ornate scarification is an integral part of the body ornamentation community, yet it has historic roots reaching far back into our evolutionary history. Before individuals began using scarification to systematically ornament their body, scars were the outcome of (sometimes battle) wounds. They were maps to an individuals' past, each telling a story of past hardships. Some particularly large scars can indicate near death experiences in which an individual overcame great odds to remain alive. Humans quickly realized that the momentary pain of cutting the skin in an artistic fashion resulted in permanent ornate designs in the skin via scarification.

Scarification as a Right of Passage

In Australia, scarification practices are practiced among Aboriginal individuals as a right of passage. Between the ages of 16 and 17, women and

men are intentionally scarred on their chests, shoulders, and bellies. Without these scars, members of the tribes are not allowed to partake in cultural customs and other tribal activities. In the Sepik region of Papua New Guinea, the people believe that crocodiles created humans. Bamboo is cut into sharp slivers and used to cut slices into a young man's chest and the entirety of his back down to his buttocks. These cultural practices are more instances of costly signaling; especially since the cultures that scarification practices originated in did not have access to modern medical interventions (so having open wounds was particularly risky).

Badges of Honor

Another form of scarification is a byproduct of a slightly different form of body modification: suspension. Suspension practices would be categorized as multiple semi-permanent deep tissue piercings strung together used to suspend an individual's body off the ground. People who practice suspension often start with hovering off the ground for a few minutes and then eventually escalate to basically being able to swing in the air weightlessly for long periods of time. Historically, suspension practices are originated in both Hindu and Mandan religious life. The Mandan are a native tribe that was located along the Missouri River that explicitly practiced suspension. During their *Okipa* ceremony, individuals were pierced and suspended as part of a story about the creation of the earth and as a rite of passage for their warriors. Though suspension would qualify as deep tissue piercing, individuals who practice this regularly wear their suspension scars as badges of honor – not necessarily as a form of ornate art, but as an indicator of an ability to do something that only a small portion of the population would dare do.

During the Hindu festival of *Thaipusam*, individuals take part in a practice referred to as *vel kavadi* in which some type of hardship must be endured. Some pierce their face with skewers, while others pierce their backs with hooks and attach ropes to them to tow various size objects:

The size of the object and amount of pain endured is supposed to indicate the amount of devotion that individual has for their worship. Though these practices are not always explicitly about suspending one's body, the repeated piercing year after year to indicate devotion leaves lasting scars that indicate many things about an individual depending on their culture.

Conclusion

Today, culture is a melting pot of many other cultures and time periods, allowing many westernized societies the luxury of sampling various practices with the assurance of modern medicine to back them up. Tattooing and piercing are nearly commonplace, and scarification is gaining some popularity within various social groups. Some tattoo and piercing shops actually specialize in precise scarification with the use of a scalpel and medical cutting techniques. Across cultures, we see scarification practices as considerably well received if it is based in historical practice and individuals are taking precaution against blood born pathogens and disease.

Definition

Pleasure felt in response to learning of another person or group's misfortune.

Introduction

Schadenfreude is a portmanteau of the German words *schaden*, harm, and *freude*, joy. Although

the word “schadenfreude” has no English language equivalent, there is a word for it in many other languages, including Dutch, Greek, Chinese, and Russian (van Dijk and Ouwerkerk 2014). Children as young as 24 months old have expressed schadenfreude when a minor misfortune has befallen a preschool friend with the seemingly unfair advantage of their mother's exclusive attention (Shamay-Tsoory et al. 2014). Thus, there is linguistic evidence for schadenfreude's cross-cultural universality and empirical evidence for its emergence early in social development. In addition, Buss (2000) has noted that schadenfreude may be an evolved psychological mechanism designed for successful competition, and research on schadenfreude has supported this notion. Schadenfreude occurs because it should feel good when competitors suffer, as such suffering often directly or indirectly leads to increases in one's relative status. As would be expected given that few competitive contexts are more consequential than the competition for desirable mates, recent evolutionary social psychological research has shown that gender-based differences in schadenfreude may reflect that one of its functions is as an indicator of positive change in one's relative mate value (Colyn and Gordon 2013; van Dijk et al. 2015). In addition to its adaptive role in competitive interpersonal contexts, schadenfreude also figures powerfully in competitive intergroup contexts, especially when the stakes are high, and the pleasing benefits are keen (Cikara et al. 2011).

Origins of Schadenfreude

By definition, schadenfreude's antecedent is the perception of another person or group's misfortune. The underlying reasons for that happiness will vary widely, as schadenfreude occurs as a result of an appraisal that a negative event that has befallen another has simultaneously advanced one or more important personal concerns, be they specific motives or broad goals (Frijda 1988; van Dijk and Ouwerkerk 2014). Not surprisingly, research shows that, for example, schadenfreude is especially likely when another one envies

suffers a misfortune, as that misfortune will often reduce the painful gap in status between the self and the other (Floyd et al. [in press](#); see entry “Fall of ‘Tall Poppies’” for a review).

Enjoying Potential Romantic Rivals’ Downfalls

As noted, schadenfreude often flourishes in the crucially important context of mating. Men and women tend to pursue somewhat different mating strategies and place different degrees of emphasis on a number of qualities of their mates as a result of differences in parental investment and different needs for maximal reproductive success (Colyn and Gordon [2013](#); Trivers [1972](#)). Among the qualities that same-sex individuals compete on in the struggle to attract the highest-quality long-term mate possible are physical attractiveness and social status, and thus Colyn and Gordon ([2013](#)) reasoned that schadenfreude might occur when a local competitor suffers a setback in those and other areas (e.g., interpersonal popularity), signaling the potential that the schadenfroh person might indirectly benefit as a result. A widespread tendency among people to experience schadenfreude in the context of mating-relevant events, they reasoned, might therefore have evolved as a result of increased fitness among those who experienced schadenfreude following a potential rival’s downfall, signaling to them that their relative mate value has increased, creating opportunities to pursue “new, additional, or better mates” (Colyn and Gordon [2013](#), p. 525). The degree of that schadenfreude, they further reasoned, should be greater among females when a close, same-sex friend suffers a decline in physical attractiveness than in social status, with the opposite being the case among males, who should feel greater schadenfreude when a close, same-sex friend’s social status declines. That is, gender-based differences in schadenfreude should emerge on the basis of the degree to which one’s mate value has increased.

Responses to both recalled and hypothetical misfortunes happening to participants’ close friends of the same sex supported Colyn and

Gordon’s predictions consistently for females and substantially less consistently for males across two studies. Subsequent work by van Dijk et al. ([2015](#)), in which schadenfreude targets were acquaintances (rather than close friends), replicated Colyn and Gordon’s results for females (e.g., that schadenfreude was greater when a same-sex acquaintance suffered a decline in physical attractiveness than when her social status declined). However, they also found *consistent* evidence that males do indeed feel happier when a same-sex acquaintance loses social status than physical attractiveness. Moreover, schadenfreude differed among neither females nor males on the basis of whether declines were in looks or social status when such misfortunes were suffered by *opposite-gender* acquaintances. Taken together, Colyn and Gordon’s and van Dijk et al.’s results suggest that schadenfreude facilitates successful competition for mates in sex-specific ways consonant with evolutionary psychological theory.

Enjoying Out-Group Misfortunes

Schadenfreude at the intergroup level entails some of the same competitive processes as those in interpersonal contexts. Naturally, people feel good when an out-group suffers because one’s own group is likely to gain as a result. However, social neuroscience research suggests schadenfreude following out-group mishaps may actually encourage a desire to take direct action against members of hated out-groups. For example, in an fMRI study assessing avid major league baseball fans’ responses to a hated rival team’s simulated misfortunes (i.e., bad plays), greater activation of the ventral striatum, a neural structure implicated in both rewarding feelings and approach motivation, was associated with greater self-reported willingness to aggress against fans of a rival team weeks later (Cikara et al. [2011](#)). In line with such findings, schadenfreude may play an especially powerful role in motivating aggression in intergroup contexts. Such contexts often weaken moral prohibitions against harming others, perhaps as a result, in part, of evolved “tribal instincts” encouraging the acquisition of

valued, reproductively relevant resources, such as territory or mates, via coalitional acts of intergroup violence (Cikara et al. 2011; Van Vugt 2009).

Conclusion

Schadenfreude is an “opportunistic” emotion not only in the sense that one has not personally brought about the competing party’s misfortune. At a deeper level, schadenfreude indicates an opportunity has presented itself to adaptively recalibrate one’s behavior, such as through seeking out better mates or striking while the enemy group is down.

Definition

Psychiatric condition characterized by delusions, hallucinations, and/or disorganized speech, as well as by grossly disorganized or catatonic behavior and/or negative symptoms. The symptoms must have persisted for at least 6 months and affect interpersonal, academic, or occupational functioning.

Introduction

The term “schizophrenia” refers to a group of disorders characterized by severe cognitive, emotional, and behavioral symptoms, which typically include the presence of delusions, hallucinations, disorganized speech or behavior, and the development of negative symptoms such as abulia, apathy, or social withdrawal (American Psychiatric Association 2013). Schizophrenia becomes usually clinically apparent in late adolescence or early adulthood. However, in many cases there are precursor symptoms in childhood, and attenuated psychotic symptoms or brief self-limiting psychotic episodes may precede the onset of the disorder. Research suggests that schizophrenia is phenotypically similar across cultures, though a more malignant course and outcome is more frequent in first-world societies. The dogma of cross-culturally equal prevalence and incidence rates of schizophrenia has recently been challenged and may need to be revised (McGrath 2006). Twin and adoption studies clearly demonstrate that genetic factors play a significant role in the trans-generational transmission of schizophrenia; however, there are important environmental risk factors contributing to the manifestation of schizophrenia, including male sex, migration, urbanicity, areas with a lower ethnic density of a minority population, and abuse or neglect during childhood (reviewed in Abed and Abbas 2011). Diathesis-stress models of schizophrenia suggest that prenatal conditions also affect the risk of developing schizophrenia, among which intra-uterine virus infections, poor nutritional status, or exposure to toxic substances during the fetal period are commonly accepted. Early disruption of neural development caused by these adverse events may be followed by a second (possibly social) incidence around puberty, when the brain undergoes dramatic reorganization (Insel 2010).

Aside from the fact that even a conservative estimate of 1% prevalence rate of schizophrenia in the general population exceeds what one would expect to occur by chance due to a high mutation rate, there is evidence to suggest that the fecundity of people with schizophrenia, particularly men, is reduced by about 50% compared to unaffected

individuals. These findings create an evolutionary enigma, because it is unclear why genes that are associated with an increased risk for schizophrenia are maintained in the genepool of a population in spite of the dramatic reproductive disadvantage associated with the condition.

Evolutionary Accounts of Schizophrenia

A plausible explanation for this puzzle is that genes associated with the condition, though increasing the risk for schizophrenia, convey advantages in terms of survival or reproduction (balanced polymorphism), or that these genes interact with other fitness-promoting genes in beneficial ways (epistasis). Following this approach, an almost countless number of hypotheses exist regarding possible advantages of genes carried by affected individuals, by nonaffected kin of index patients, or advantages for the social group (group selection approaches; overview in Polimeni and Reiss 2004). These hypotheses comprise ideas concerning adaptive properties of schizotypal traits in relation to group selection, schizophrenia as a trade-off of human language acquisition or creativity, reduced risk of cancer in relatives of schizophrenia patients, schizophrenia as an extreme phenotype produced by variation of sexually selected traits, and effects of maternally imprinted genes (reviewed in Brüne 2016). A problem of these approaches is that many of them implicitly assume that schizophrenia is a homogenous “disease entity,” or that the risk for schizophrenia is conveyed by a single gene or a few genes with large effect size, which is currently not supported by empirical evidence (Keller and Miller 2006). However, there is some evidence for positive selection in the human lineage at several loci including those coding for DISC1, dysbindin, and neuregulin, which are known to be involved in neurodevelopment (Crespi et al. 2007).

As space is limited, two plausible scenarios are highlighted in the following paragraphs, one concerning a genetic approach and the other a more environmental slant.

With regard to a possible role of sexual selection in schizophrenia, an interesting hypothesis

posits that these disorders represent “low-fitness variants” of sexually selected traits (Shaner et al. 2004), which may explain why patients with schizophrenia have reproduction rates below average. It could also account for recent reports about a relationship of age at onset of schizophrenia varies and latitude suggesting that onset is earlier in populations living closer to the equator. For example, it could be that increased exposure to pathogens and higher levels of polygyny create pressure on shifting mating to a younger age. Consequently, a dopamine overshoot in the ventral striatum may lead to earlier expression of schizophrenia-associated signs and symptoms, when the need for premature courtship behavior serves as nonspecific stressor. Moreover, since stabilizing selection tends to reduce deleterious mutations, it could be that an individual’s higher than average number of fitness-reducing alleles leads to the expression of a schizophrenia phenotype, though many of these alleles may be evolutionarily transient. Thus, the emergence of new fitness-decreasing mutations may contribute to an equilibrium through which the average prevalence of schizophrenia in a population is maintained. Such a scenario may also explain why the replicability of findings concerning genes conferring risk for schizophrenia is difficult (Shaner et al. 2004).

Consistent with the hypothesis of schizophrenia as maladaptive extreme of variation of sexually selected traits, there is some evidence for genomic imprinting in schizophrenia. For instance, maternal imprinting could be associated with a general undergrowth and “femaleness” of the brain in schizophrenia, indicated by lower gray matter volume, diminished lateralization, and hyperactive social cognition producing delusions of reference – the opposite of what is typical for autism in which paternal imprinting may prevail (Crespi and Badcock 2008).

Aside from these genetics-oriented hypotheses, approaches taking into account environmental risk factors suggest that schizophrenia may arise from a mismatch between ancestral and current environments, whereby schizophrenia (foremost those phenotypes associated with

paranoid ideation) could be the extreme of variation concerning the intolerance of outgroup membership (Abed and Abbas 2011). In support of this idea, the anthropological record of *Homo sapiens* indicates that, for the most part of their evolutionary history, humans have lived in small-scale communities associated with xenophobic attitudes towards strangers. Culturally determined interaction with large numbers of people who are personally unknown may produce heightened vigilance, fear of being assaulted by others, and suspiciousness with regard to others’ malicious intentions. In vulnerable individuals, exposure to novel environmental conditions brought about by migration, urbanicity, poverty, or ostracism may then culminate in psychosis (Abed and Abbas 2011). Predictions derived from this hypothesis include higher rates of schizophrenia in males, in people who migrated to other countries or social systems (extending to the second generation), in those who have experienced exclusion from the community or social defeat, and in young people during adolescence (i.e., changing role models and social expectations). Consistent with the “outgroup intolerance hypothesis,” the content of persecutory delusions has been found to differ between men and women regarding the number and sex of persecutors, as well as regarding the degree of familiarity with the perceived persecutor. That is, whereas men usually feel more often threatened by groups of strange males, women more often feel persecuted by individuals from their personal environment. Both deluded men and women primarily report fears of being physically injured or assaulted. Indeed, in stone-age conditions, the main threat for men was presumably being assaulted by men from other tribes; women, by contrast, were more threatened by exclusion from the community (reviewed in Brüne 2016).

Conclusion

Evolutionary hypotheses about schizophrenia are abundant, but many are difficult to test empirically. Potential pitfalls concern the heterogeneity

of the phenotypic picture, shaky boundaries between psychosis and “normalcy,” and uncertain diagnostic validity of “core” symptoms of schizophrenia (Brüne 2016). There is clearly a need for addressing open genetic questions to resolve the question of why schizophrenia is associated with high heritability, high prevalence, and low reproductive fitness, and what the role of immune function of “risk” genes for schizophrenia might be (Flint and Munafò 2014).

Definition

Bullying is most commonly defined based on Olweus's (1993) definition that includes three elements: (a) an imbalance of power, (b) intent to harm, and (c) is repeated over time. Recently, an alternative definition that integrates recent theory and empirical data has been proposed: “Bullying is aggressive goal-directed behavior that harms another individual within the context of a power imbalance” (Volk et al. 2014, p. 328).

Introduction

Bullying, a subset of aggressive behaviors, is a construct that often elicits strong opinions. Some people believe that bullying is a part of growing up or a *rite of passage* that “builds character,” while others view it as a severe problem that can be harmful, even detrimental, to those involved. Bullying can be understood as a “unique but complex form of interpersonal aggression, which takes many forms, serves different functions, and is manifested in different patterns of relationships” (Swearer and Hymel 2015, p. 344). Olweus's (1993) definition illustrates bullying as intentional versus accidental; this is generally agreed upon by bullying researchers. Further, some researchers have linked bullying to proactive aggression, which is consistent with the idea that bullying is goal-oriented (Volk et al. 2014). To understand the complexity of school bullying,

the following factors are discussed: common theoretical perspectives, who is involved in bullying, types of bullying and prevalence rates, the impact of school bullying on youth, and prevention and intervention services.

Theoretical Perspectives on Bullying

The importance of theoretical perspectives in bullying is that they provide a means to understand the underlying causes of bullying – specifically why some youth bully others and why some youth are bullied or victimized – and that they can be applied to guide the development of interventions. Several theoretical perspectives have been used in research to understanding bullying, ranging from theories that explore individual characteristics that contribute to bullying behaviors to ones that examine the broader context – the systems within which the bullying takes place – and the relationship between the context, the individual, and the bullying behaviors. Three theoretical perspectives are discussed below.

Social Ecological Theory

Social ecological theory, more commonly referred to as ecological theory (Bronfenbrenner 1979), has been applied extensively throughout the aggression literature and has also been used throughout the bullying literature. The social-ecological framework has been used to understand systems (i.e., micro-, meso-, exo-, macro-, and chronosystems) that impact bullying and to create prevention and intervention programs effectively relevant to various settings (Espelage 2014). From this theoretical perspective, bullying is construed as an event that is influenced by multiple factors, including: individual characteristics, interactions with others (e.g., peers, families, teachers), and the influence of the varying contexts within which they exist (Swearer and Hymel 2015). This framework has been used to examine concepts such as school climate, peer-to-peer relationships, family dynamics, and bystander roles as they relate to bullying. More recently, technology has been viewed as a subsystem and proposed as an addition to the social

ecological model as the techno-subsystem (Johnson and Pupilampu 2008) that is a “...dimension of the microsystem...[and] includes child interaction with both living (e.g., peers) and nonliving (e.g., hardware) elements of communication, information, and recreation technologies in immediate or direct environments (p. 23).” The techno-subsystem is purported to influence the relationship between the child and the microsystem by acting as a mediator. It is likely that, as research evolves to support the techno-subsystem, this element of the social ecological framework will be applied the bullying literature, particularly in the examination of cyberbullying.

Evolutionary Theory

Some researchers have applied evolutionary theory to understanding aggression, which has been useful and suggests the utility of this theoretical approach for understanding bullying (Volk et al. 2014). This is not surprising as bullying is functionally adaptive across several social animals (Volk et al. 2016). Evolutionary theory posits that bullying serves certain functions that lead to positive outcomes, such as resources and reputation, implying that bullying is a goal-directed behavior (Volk et al. 2014). This theoretical perspective posits that there are benefits tied to bullying others. For example, the bully may be viewed as more attractive by others and may be perceived as popular or having social status (Volk et al. 2016). In this case, evolutionary theory suggests that the bullying persists because it continues to be adaptive (Volk et al. 2014). This is not meant to imply that bullying is without consequences, but rather that the underlying goals may outweigh potential negative consequences. This further illustrates the complex nature of bullying.

General Strain Theory

General strain theory (GST) is a theory that is popular in contemporary criminology and is a newer theoretical framework that is being applied to understanding traditional bullying and cyberbullying (Patchin and Hinduja 2011). GST suggests that when individuals experience strain, it

can lead to a range of negative emotions (e.g., frustration, anger), which increases the likelihood of engaging in delinquent behavior (Agnew 1992). Patchin and Hinduja (2011) argue that two of Agnew's (1992) major types of strain have potential relevancy for understanding bullying: (a) threat or actual presence of a negative stimuli, and (b) the loss or threat of loss of a positive-valued stimuli. A few studies have examined traditional bullying and/or cyberbullying as potential outcomes of strain (type a) and found a direct relationship between strain and both types of bullying (e.g., Keith 2017; Patchin and Hinduja 2011). Other researchers have found support for peer victimization (or experiencing bullying) as the source of strain (type b) that leads to delinquent or problematic behaviors (e.g., Baker and Pelfrey 2016).

Who Is Involved in School Bullying?

When considering bullying as a dyad, most people identify the victim (or target) and the bully (or perpetrator). Researchers have also identified bully-victims and bystanders as having substantial roles in the bullying dyad.

Bully

The *bully*, also referred to as a perpetrator, is the individual who harms another person or group of people through use of aggressive behaviors (e.g., physically hurting, calling names, excluding). There are several myths about who the bully is, such as the stereotype perpetuated by the social skills deficit model that suggests a bully may have power over others, but is socially incompetent (Hymel and Swearer 2015; Sutton et al. 1999). Sutton et al. (1999) suggest that while social-emotional deficits can contribute to aggression, contextual factors such as peer group and environmental influences also need to be considered. Sutton and colleagues (1999) defined two different roles for the bully: the ringleader and the follower (one who accompanies the ringleader). The ringleader bully may have power over the supporter bullies, and by imitating the leader's behavior, supporters may feel a sense of

belonging to a clique. Another common stereotype that research has clarified is that a bully has low social status and is not liked at all by peers. Volk and colleagues (2014) noted that several research studies have demonstrated that peers perceive bullies as being dominant and popular even though they are rated lower on likeability. In short, the myths about bullies cannot be accepted as facts, and inferences ought not to be made over these myths.

Victim

Victims, also called targets, are individuals who are on the receiving end of bullying from others. Researchers have identified different types of victims such as passive victims and provocative victims (whose offensive behaviors may elicit bullying from others; Olweus 1997). Victims are often described as having low self-esteem, poor interpersonal skills, and difficulty in building friendships (Olweus 2003). Further, researchers have found that victims of bullying often experience loneliness and internalizing issues (e.g., anxiety, depression), and low self-esteem (Swearer and Hymel 2015).

Bully-Victim

Bully-victims are students who both bully others and are victimized by others; this group has been identified as distinct from bullies (Olweus 1993). Bully-victims are often considered a subtype of bullies, sometimes called reactive bullies, and are seldom discussed under the characteristics of victims (Volk et al. 2012). However, the literature shows that there are substantial differences between nonvictimized bullies and bully-victims. It is hypothesized that bully-victims are more likely to engage in reactive bullying, whereas nonvictimized bullies are more likely to use proactive aggression (i.e., aggression that serves a purpose; Volk et al. 2012). Research has consistently demonstrated that bully-victims tend to experience poorer outcomes in comparison to victims and bullies (Volk et al. 2012).

Bystander

Bystanders are the individuals who observe bullying, are present in the vast majority (around

85%) of bullying incidents, and can often have an effect on bullying incidents (Swearer and Hymel 2015). The main roles of bystanders include reinforcer, assistant, outsider, and defender (Salmivalli et al. 1996). *Reinforcers* mostly support the aggressive and offensive behavior of the bully by laughing at the victim and/or cheering on the bullying. *Assistants* actively engage in the bullying incident and take part in harassment. The *defenders* attempt to protect the victim and stop the bullying. Lastly, a bystander may take the role of *outsider*; in this role, the bystander has no direct involvement in the bullying incident but acts as a silent approver through inaction. Interestingly, Salmivalli and colleagues (1996) found that girls were more likely to assume defender and outsider roles, while boys were more likely to be reinforcers or assistants.

Prevalence Rates

No child or adolescent is necessarily immune to school bullying, though there are some factors that increase the risk and/or likelihood for some individuals to be more likely to be involved in bullying. Some of these factors include age or grade level, gender, and individual characteristics. School bullying is observed as early as in pre-school and generally peaks during middle school (around ages 11 through 14) and somewhat decreases toward the end of high school (Hymel and Swearer 2015; Nansel et al. 2001). Youth in middle school are likely to be at the greatest risk for involvement in bullying. Prevalence rates can vary widely dependent upon how it is defined and measured. In general, overall prevalence rates range from about 30% to 35% of youth reporting involvement in bullying in some capacity (Currie et al. 2012; Hymel and Swearer 2015; Nansel et al. 2001). Hymel and Swearer (2015) conducted a review of the past four decades of research and found that 10%–33% of students reported being bullied by others (victims and bully-victims) and 5%–13% reported bullying others (bullies and bully-victims). A study by the World Health Organization (WHO; Currie et al. 2012) examined bullying across 43 countries and reported

prevalence rates ranging from 2% to 32% for victimization and 1%–36% for bullying others. These prevalence rates of victimization and bullying are inclusive of victims, bullies, and bully-victims. Bully-victims are often a smaller group with prevalence rates ranging from 1% to 12% (Hymel and Swearer 2015). Prevalence rates can vary based on several factors such as how bullying is defined, how bullying is assessed (e.g., self-report, peer nominations, teacher report), the specific type of bullying, and sample characteristics.

Types of School Bullying

Olweus (1993) classifies the types of bullying as direct and indirect forms; they have also been referred to as overt (e.g., physical) and covert (e.g., relational). As the terms imply, direct bullying refers to visible attacks against the victim and indirect bullying refers to covert actions that are less easily seen (e.g., exclusion from a group, rumor spreading, and gossiping). Recent literature suggests four common types of bullying that are classified as: physical bullying, verbal bullying, relational aggression/bullying, and cyberbullying.

Physical Bullying

Physical bullying is defined as harming others and their property in a repeated way via the use of physical force and includes the threat of physical damage such as kicking, hitting, hair pulling, stealing, and attacking with a weapon (McGrath 2007). This type of bullying is considered easier to detect because physical attacks are overt and observable. Victims of physical bullying are usually weaker physically and have less power. Researchers have found that male students are much more likely to engage in physical bullying compared to female students, while females *may be* more likely to engage in relational, verbal, and cyberbullying, though gender differences are not always evident across these types of bullying (e.g., Hymel and Swearer 2015).

Verbal Bullying

In contrast to physical bullies, verbal bullies seek victims who are weaker in terms of their social

status (e.g., unpopular, new in the school, having low SES; Sonneborn 2013). Verbal bullying includes behaviors such as name-calling, insults, and threats. Students might perceive name-calling or insults as a part of childhood or adolescence rather than a serious form of bullying. Distinguishing teasing from verbal bullying can sometimes be a challenge for youth and for researchers. In past studies, threatening other's physical health has also been included in the definition of verbal bullying. According to Rivkin (2013), verbal bullying happens two times more than physical bullying – regardless of age, SES, gender, and ethnic status.

Relational Aggression

Various terms are used throughout the bullying literature interchangeably with relational aggression, including social aggression and indirect aggression, though researchers may define these constructs somewhat differently. *Relational aggression* is defined as harming others through damage, or the threat of damage to end relationships, to exclude from the group, or to lose feelings of acceptance (Crick et al. 1999). Relational aggression differs from the previous forms of bullying in that its main focal point is to harm interpersonal relationships (Crick et al. 1999). As the name implies by *indirect aggression*, the victim is not confronted by the hostile behavior in an explicit way. For instance, rumor spreading and ignoring are the most frequently used forms of indirect aggression. However, relational aggression conveys all hostile behaviors, including both indirect and direct actions (Crick et al. 1999). Crick and colleagues (1999) suggest that *social aggression* is a broader term than relational aggression and the difference between these terms is that while relational aggression includes the intention of harming relationships, social aggression does not require this intention. This includes verbal insults, rumor spreading, negative facial and body expressions, and physical aggression.

Cyberbullying

Cyberbullying refers to bullying that occurs through electronic devices (e.g., computers, cell

phones, etc.) with the goal of hurting someone else (Peterson 2013). Other terms (e.g., online bullying, internet bullying) have also been used; however, cyberbullying is the most commonly used term. Cyber-bullies mostly harm their targets through rumor spreading in online platforms, threats of harm via text messages, sending sexualized posts, racist rhetoric comments on the social media channels, or leaving out from a group chat (McGrath 2007). Cyberbullying is different from traditional forms of bullying in that bullies have anonymity – they can hide behind their screen. This anonymity and distance from the victim contributes to the bully feeling emboldened and engaging in more insulting and hurtful language than they might use when face to face (McGrath 2007).

Instant messages, social media sites, pictures or videos, phone calls, emails, weblogs, and so forth are most commonly used to cyberbully (McGrath 2007). Cyber-bullies may possess multiple accounts on social media sites or apps (e.g., Snap Chat, Facebook, Twitter, YouTube, etc.) and use their fake accounts as a tool for bullying, soliciting personal information, pictures, etc. from potential victims. Cyber-victims are not as easily able to escape from these stimuli and can be exposed to this bullying regardless of place or time (McGrath 2007). Though some have noted that youth can disconnect from technology to escape the bullying, technology has become an aspect of life that is often heavily integrated both socially and academically.

Impact of Bullying on Youth

Extensive literature has examined the impact of bullying on youth involved and found that all individuals are negatively impacted by the experience, with bully-victims experiencing the worst outcomes (Swearer and Hymel 2015). Bully-victims experience greater risk for several issues such as internalizing issues, low self-esteem, suicidality, and substance abuse. Swearer and Hymel's (2015) review of the literature found that victimization is related to a host of problems including poor physical health, poor social

adjustment, peer rejection, and internalizing (e.g., anxiety, loneliness) and externalizing (e.g., hyperactivity, delinquency) issues. The authors note that while these issues can result from victimization, some of these may be antecedents to the bullying. Bullying perpetration is also related to several problems such as further aggressive behavior, conduct problems, and internalizing issues (Swearer and Hymel 2015).

Effective Prevention and Intervention

There are numerous school-based prevention and intervention programs that have been developed to address bullying. These programs typically address school-wide populations, small groups of students, or individuals. Some programs also promote parent/caregiver or familial involvement and include community partners. In addition to formal prevention and intervention programs, many schools adopt anti-bullying policies or integrate anti-bullying information into existing policies.

School-Wide Bullying Prevention

Although there is a wide variety of programs that claim to decrease bullying behaviors, few programs have been researched thoroughly enough to be considered empirically supported. Programs such as *Bully Busters*, *Expect Respect*, *KiVa*, *Olweus Bullying Prevention Program*, and *Bully-Proofing Your School* are commonly implemented programs that have undergone sufficient research to be considered evidence-based. Two of these programs will be discussed in greater detail, followed by a discussion of anti-bullying policies.

Bully Busters. The Bully Busters program has demonstrated effectiveness in addressing the issue of bullying. The overarching goal of Bully Busters is to promote a safe and healthy learning environment for students through enhanced social environments and decreases in bullying behaviors. This program increases awareness of bullying among educators and teaches students to reject bullying as an acceptable behavior. Bully Busters also includes a parent and family guide which

promotes bullying awareness and provides additional information for how to support children who may be affected by bullying behaviors.

Several published studies have evaluated the effectiveness of Bully Busters at the elementary and middle school levels and found positive teacher and student outcomes (e.g., Browning et al. 2005; Newman-Carlson and Horne 2004). For example, Newman-Carlson and Horne (2004) evaluated a treatment and control group of middle school teachers to evaluate the effectiveness of the Bully Busters training curriculum for teachers. Results revealed a significant increase in teachers' bullying knowledge and an increase in use of bullying intervention skills. Furthermore, an examination of disciplinary referrals demonstrated a significant decrease in students' bullying behaviors.

Bully-Proofing Your School. Bully-Proofing Your School (BPYS) is an empirically supported program that includes teacher training and a student curriculum. Teacher training is comprised of disseminating important information, including: (1) definitions, (2) understanding the roles and characteristics of bullying, (3) recognizing the impact of bullying on learning and social-emotional outcomes, and (4) reviewing the student curriculum and practicing teaching it. The student curriculum includes explicit instruction of definitions, establishing anti-bullying rules, learning techniques for protecting against bullying, and learning how to stand up against bullying. Role plays, recognition, and rewards are three tangible steps to student understanding and buy-in.

Empirical literature measuring the effectiveness of the BPYS Program demonstrates positive outcomes, which includes decreases in bullying behaviors and increased perceptions of school safety, particularly at the elementary level (e.g., Beran and Tutty 2002; Menard and Grottpeter 2014). Menard and Grottpeter (2014) surveyed nearly 3,500 elementary-age students across six elementary schools to measure the effectiveness of the BPYS Program. Results indicated that the schools which implemented the BPYS Program treatment had significantly reduced bullying behaviors and increased perceived school safety as compared to the control group.

School-Wide Bullying Policies. One popular approach to addressing disruptive behaviors is the implementation of zero tolerance policies. The literature regarding this authoritarian approach to discipline suggests that zero tolerance policies are ineffective methods of addressing bullying and may increase negative mental health outcomes for students (American Psychological Association Zero Tolerance Task Force 2008). More effective approaches may include: (1) the implementation of school-wide positive behavioral interventions and supports (PBIS), (2) small group interventions that enhance social skills and/or teach students healthy coping skills, or (3) cognitive-behavioral therapy for at-risk students.

Although zero tolerance policies are not appropriate for addressing bullying prevention and intervention, whole-school policies related to bullying may be beneficial. Olweus (1997) suggests that developing school-wide goals for decreasing bullying behaviors and creating standardized guidelines for addressing these behaviors is helpful. To the greatest extent possible, the development of these policies should be collaborative in nature, including educators, families, community members, and students (when appropriate).

Targeted Prevention and Intervention

Unfortunately, no school-wide prevention program or policy is 100% effective. Therefore, more targeted prevention and intervention strategies are necessary to address the needs of children who are at risk for or engaged in bullying behaviors. Two effective evidence-based targeted prevention and intervention strategies are the *Method of Shared Concern* and social skills group interventions (Rigby and Griffiths 2011).

Method of Shared Concern highlights the social dynamics of bullying behaviors. This targeted intervention is appropriate for small groups of youth who have been identified as having involvement in bullying either as bullies or victims. A qualified and trained professional individually interviews the suspected bullies and explicitly shares concern for the student who is a target of bullying. After these interviews, the same practitioner will meet with the student who is a target of the bullying behaviors to provide support

and talk through the situation. A final meeting, known as a summit meeting, is held in which the target student(s) and the suspected bully or bullies come together with the trained professional to resolve the problem.

Intensive School-Based Intervention

The existing literature on bullying and school-based prevention and intervention is limited with regards to intensive intervention. Felix et al. (2014) suggest that no literature is available that supports the explicit, intensive intervention of chronic bullying and bullying victims. However, individuals who may require intensive intervention for bullying may display additional concerns related to depression, anxiety, or aggression. In these circumstances, a school-based mental health professional such as the school psychologist may conduct an assessment and/or refer the student for appropriate school or community services that can provide adequate, evidence-based treatment(s).

Additional Considerations

Educators and other professionals who work with youth at risk for or engaged in bullying should be knowledgeable about issues of diversity, including the social and political climates that can contribute to bullying behaviors in schools. In an effort to create safe and positive learning environments for all students, school-based bullying prevention and intervention programs should take into consideration the unique strengths and needs of the student body. In particular, minority students may be at an increased risk for victimization due to race, sexual orientation, special education status, or immigration status (among many other variables).

Conclusion

School bullying is a problem for many youth and it does not appear that bullying will cease to exist in schools any time soon, or possibly ever if it is to be believed that this construct serves an evolutionary purpose. Regardless, given the impact that school bullying has on many youth involved – either directly or indirectly – it is important that

schools address bullying through both prevention and intervention efforts.

Definition

The school environment encompasses institutional and structural features (e.g., size, space, structural organization, availability of resources), social relations (e.g., teacher-student relationships, relations between students), teaching and learning (e.g., quality of instruction), physical and social-emotional safety, as well as shared beliefs, values, and attitudes (that are often referred to as school culture or school climate).

Introduction

The school is an important microsystem that affects the personality development of students, in general, and their development of academic skills in particular. Students spend more time at school than at any other place outside their homes. For example, adolescents from Europe and the USA spend about 37% of their waking hours at school (Alsaker and Flammer 1999). While scholars agree upon the important role that the school environment plays in student development, they differ in the use of terminology. For example, while many researchers use the terms *school environment* and *school climate* interchangeably (e.g., McGiboney 2016; Wang and Degol 2016), others define school climate narrowly as the shared beliefs, values, attitudes, or perceptions held by students, teachers, and administrators, in contrast to more objective characteristics of the school environment, such as instructional practices and leadership (e.g., Rudasill et al. *in press*). In most cases, both views will not conflict with one another as the large majority of studies assessed the school environment via self-reports of students and/or teachers (Fraser 2012; McGiboney 2016; Wang and Degol 2016).

Aspects of the School Environment

While researchers and practitioners agree that the school environment is multidimensional, scholars have proposed different typologies for describing the school environment. Nonetheless, the majority of researchers agrees that the following four

aspects are major areas of the school environment or school climate, respectively: (a) the academic climate (such as academic tasks and instruction, leadership, and professional development), (b) relationships (teacher-student relations, peer relations, and relations between teachers in terms of level of support and connectedness), (c) physical and social-emotional safety (e.g., concepts and measures for addressing violence in the school), and (d) the institutional environment (such as environmental adequacy, structural organization, and availability of resources) (e.g., Ramelow et al. 2015; Wang and Degol 2016). These four dimensions could also be assessed at the classroom level, although contents must be adapted (e.g., school rules for misbehavior vs. behavior management practices in the classroom). In general, assessments of the school environment and of the classroom environment tend to be only weakly correlated, as related measures address different dimensions and as classrooms are somewhat insulated from the school as a whole (Fraser 2012).

Assessment

A number of measures have been developed for assessing the school environment, such as the “What’s Happening in This School?” questionnaire and the Inventory of School Climate (see McGiboney 2016; Ramelow et al. 2015), although none of them includes all of the four main domains that have been proposed. While most of these measures show satisfactory reliability, support for their validity tends to be limited. An overview of measures of the classroom environment – such as the “What is Happening in this Class?” questionnaire, the Classroom Environment Scale, and the My Class Inventory – has been provided by Fraser (2012). There is high variability in the assessed dimensions of the classroom environment, with quality of the social relationships (e.g., cohesiveness, teacher support), task orientation (e.g., class level of achievement motivation), differentiation (e.g., different students work with different materials), and organization (e.g., rule clarity) being measured most often. Some of these measures do not only assess the actual classroom environment as it is

experienced but also the preferred or ideal classroom environment. Differences between the actual and preferred environment can be a starting point for interventions.

Studies that collected data from more than one group of respondents (students, teachers, parents) indicated that the perspectives of these respondents on the school environment differ: Students tend to give less favorable reports on safety and connectedness than teachers and parents do (e.g., Ramsey et al. 2016); this is most likely an indication of the fact that adults are not aware of some existing problems the students face in their school. In addition, Ramsey et al. (2016) observed that, compared to students, teachers gave lower ratings of academic emphasis (such as teachers setting high standards for teaching) and parents rated parental involvement lower. Thus, informants may give lower ratings of dimensions of climate which are most directly related to their own behaviors. Correlations between the views of students and teachers tend to be in the moderate range (Brand et al. 2008). Ratings of students and parents on the school environment tend to be less congruent if schools have more ethnically diverse student populations and more newcomers (McGiboney 2016). These results indicate that data should be collected from more than one source in order to get a balanced picture of the school environment.

Given the fact that self-report data on the school environment are nested (students attend an individual class which is, again, part of an individual school, which is located in a particular school district), multilevel modeling is the preferred method for statistical analysis, although very few available studies have included more than two levels in the analysis. For example, Koth et al. (2008) observed that the majority of variance in student perceptions of school climate occurs at the individual level, while 8–9% of the total variance was based on classroom membership, and an additional 5–27% of the total variance of perceptions of the school environment occurred between schools. Perceptions of school safety showed stronger variations between schools than perceptions of students’ achievement orientation, such as their willingness to learn.

These results indicate important variability of perceptions of the school environment within classrooms, with male students and those from ethnic minorities tending to perceive the school less favorably.

Variations in the School and Classroom Environment

In many countries, formal education is divided into a number of distinct educational stages, such as elementary school, middle school, and high school, which differ in the school environment. In elementary school, students are typically assigned to one teacher and spend much of the day in that teacher's classroom with the same group of students. In middle and high school, students are typically assigned to a team of teachers and move from classroom to classroom over the course of the school day, in part with somewhat different groups of students in each. Compared to elementary schools, middle schools place greater emphasis on discipline and academic accomplishment and provide less opportunity for close relationships to specific teachers. High schools provide a larger, more impersonal, teacher-centered, academically demanding, and competitive school environment than elementary and middle schools, although they often allow students to make more choices in terms of academic and extracurricular activities. Research by Eccles and coworkers (for overview, Eccles and Roeser 2012) indicates that students moving from primary schools to secondary schools leads to a deterioration of the perceived classroom environment through, for example, the use of more control-oriented strategies and provision of fewer opportunities for student autonomy and decision-making in the classroom. These environmental changes are associated with an increasing mismatch between the classroom environment and students' growing needs for autonomy, competence, and relatedness. The fit or misfit between students' psychological needs and their school environment influences their motivation for academic success.

Changes in perceptions of the school environment are not limited to school transitions, as a number of studies also described a decline in school climate perceptions while students

attended the same school, such as perceptions of teacher support or clarity of school rules (e.g., Wang and Dishion 2012). It is not clear whether school climate deteriorates because of age-associated behavioral changes of the students (such as declines in seeking support from adults or increasing rates of delinquency) or changing academic demands, or whether students become increasingly dissatisfied with their schools, irrespective of a school environment which is actually rather stable.

In many countries, students of secondary schools are placed into different types of schools, hierarchically structured by performance (ability grouping or tracking). The quality of the school environment tends to vary by school track, in particular in the field of teaching and learning, as well as safety. Cognitively activating teaching is more often found in the highest track (college-bound), while teacher support tends to be highest in the lowest track (vocational-bound) (Kunter et al. 2005). Students in schools that offer academically oriented tracks also report a school climate with fewer disciplinary problems (e.g., classroom disruption, student victimizations) (van de Werfhorst et al. 2012). Low track placement has been related to poor attitudes toward school and low academic achievement, although academic self-concept may benefit due to better opportunities to compare oneself with peers with similar or worse academic achievements. There is an ongoing debate whether differences in achievement result from academic tracking or reflect pre-existing disparities (Eccles and Roeser 2012).

Association of the School Environment with Student and Teacher Outcomes

"School effects research" originally analyzed how the school environment shapes students' academic attainment and social behavior. Subsequent research examined how school factors relate to the psychological well-being and physical health of students and teachers. Up to now, the empirical evidence on effects of the school environment is limited because most available studies are cross-sectional and do not allow for drawing causal

conclusions: Academic achievement, behavior problems, or mental health of the student may also affect aspects of the school environment, such as teachers' behavior toward the individual students or the risk of being bullied. Although few cross-lagged studies have found stronger effects of the perceived school environment on changes in students' outcomes compared to students' effects on changed perceptions of the school environment (e.g., Košir and Tement 2014), Benbenishty et al. (2016) observed that a sum measure of school climate (belongingness, adult support, school participation) did not predict changes in academic achievement, while initial levels of academic achievement predicted improvements in perceived school climate. In addition, many available studies have not controlled for potentially confounding effects of family and neighborhood characteristics, as families with lower socioeconomic backgrounds and those from deprived living areas may send their children to lower-quality schools.

The following paragraphs summarize research on the associations of the four major areas of the school environment (academic climate, safety, relationships, the institutional environment) with academic achievement, problem behavior, and psychological well-being of students, based on the systematic review by Wang and Degol (2016). As studies on associations of the school environment with student health behaviors and teacher outcomes addressed only few environmental dimensions, related results will be presented in a more condensed form.

Academic Outcomes

Academic outcomes have long been examined as a consequence of variation in the school environment. A meta-analysis by Karadağ et al. (2016) found a moderate correlation between indicators of a positive school climate and academic achievement ($r = 0.36$). When focusing on individual dimensions of the school environment, the most consistent results have been found with regard to the *academic climate* and the quality of social relations. Higher academic achievement is found in schools which emphasize the importance of commitment to high academic standards and

that are characterized by effective leadership from teachers and principals, who believe in their ability to improve student outcomes. For example, students from schools that maintain higher academic standards and encourage students to do their best tend to show stronger growth in math and science achievement than other students (Hoy et al. 2006; Ma and Wilkins 2002).

A positive *relationship between teachers and students* has also consistently been related to better academic outcomes (e.g., student motivation, school attendance, grade point average). A meta-analysis by Roorda et al. (2011) identified small to moderate positive associations of teacher support and caring with student engagement ($r = 0.34$) and academic achievement ($r = 0.16$). Košir and Tement (2014) found that (student-rated) teacher support and (teacher-rated) teacher acceptance predicted improvement in grade point average over time. Studies indicated that the association between positive student-teacher relationships and academic achievement is mediated by students' classroom engagement (Wang and Degol 2016).

Higher levels of school *safety* were associated with positive changes in academic achievement in a cross-lagged study by McCoy et al. (2013). In that study, higher initial school levels of academic achievement also predicted improved perceptions of school safety over time. However, some other studies found no association between safety and academic achievement or indicated that the association between both variables disappeared when other dimensions of the school environment were controlled for (Wang and Degol 2016).

Structural/institutional characteristics of the school do not seem to directly affect student achievement, but may alter classroom processes, which could affect achievement. Studies consistently indicate that students perform better in schools where more children come from families of high socioeconomic status (SES), regardless of their individual SES; this effect is mediated through the quality of the learning environment, such as quality of curriculum and instruction and level of support within the teacher-student relations (Perry 2012). Meta-analyses have found small to moderate positive associations between school resources, such as per pupil expenditure,

and student achievement (e.g., Greenwald et al. 1996), although translating resources to student academic performance depends on how these resources are used for improving more proximal processes in the classroom, such as instructional quality (Archibald 2006). Results on associations of other institutional/structural aspects (e.g., school size, private vs. public schools, location in urban, suburban, or rural areas) with academic achievement are inconsistent and tend to disappear when more proximal processes are controlled for (Wang and Degol 2016).

Externalizing Problem Behavior

A meta-analysis by Steffgen et al. (2013) found a small to moderate negative association between sum measures of school climate and school violence ($r = -0.26$), with the size of the correlation varying between studies. As externalizing behavior refers to delinquent and aggressive behavior, one could expect that social relations (between teachers and students, as well as between students), as well as the physical and social-emotional safety at school, should show the most consistent relations with the levels of externalizing behavior of the individual student. Nonetheless, few studies indicated that a high-quality *academic environment* is also related with lower levels of externalizing behavior of the individual student in the classroom. For example, Wang (2009) found lower levels of externalizing behavior if schools/teachers emphasized mastery goals (i.e., focusing on self-improvement, effort, and true understanding) rather than achievement goals (i.e., focusing on the attainment high grades and outperforming others). The statistical effects of mastery goal orientation might be based on the promotion of more positive relations with peers within the classroom and the investment of more time for learning after school rather than misbehaving.

Associations between the *quality of interpersonal relationships* within the school and experiences of bullying, aggression, and delinquency have been observed in many studies. For example, a meta-analysis by Ali et al. (2015) revealed a small negative correlation between perceived

teacher acceptance and students' conduct problems at school ($r = -0.22$). Nonetheless, evidence for causal effects of teacher support/acceptance on externalizing problems still has to be established. For example, Leflot et al. (2011) did not find effects of teacher support on change in students' externalizing behavior over time. With regard to social relations between students, the meta-analysis by Cook et al. (2010) indicates that students who are less accepted by their peers are more likely to bully their classmates and to be bullied by them. Longitudinal studies on bidirectional associations between aggression and peer status have found that physical aggression predicts peer rejection, which in turn, predicts subsequent increases in aggression (e.g., Lansford et al. 2010).

The *safety* of the school environment shows negative associations with aggressive behavior and bullying victimization of the individual student. Schools in which safety rules are effectively enforced, and schools with better discipline management, have lower rates of student victimization and delinquency, but available results are mainly based on cross-sectional data (e.g., Gottfredson et al. 2005).

Associations of *institutional/structural variables* – such as student-teacher ratios, poverty concentration, and suspension rates – with externalizing problem behavior at school may be indirect, by influencing the opportunities for aggressive and delinquent behavior at schools and the consequences of these behaviors (Wang and Degol 2016).

Students' Psychological Well-Being

There is very limited research on the association of *academic climate* with psychological well-being of children and adolescents. Nonetheless, Wang (2009) observed that school endorsement of a mastery goal structure (emphasis of effort; expectations that all students can improve their skills) was related to lower levels of depression, most likely due to the focus on individual progress. In contrast, school endorsement of achievement goals (such as pressuring students to acquire high grades and outperform others) was associated with higher levels of depressive symptoms,

as low-achieving students receive consistent negative feedback about their performance.

Most available research on the association of the school environment with psychological well-being has focused on *social relationships* between students and teachers, or between students. More concretely, supportive teacher-student relationships, respect for students' opinions, and measures that promote feelings of school belonging are robust predictors of students' emotional health (Wang and Degol 2016). Changes in perceptions of teachers' support have also been found to reliably predict changes in students' self-esteem and depression (Reddy et al. 2003).

Positive associations of *school safety* with psychological well-being have been identified in a few studies, for example, because students from safe schools are protected against negative feelings associated with peer harassment (see Wang and Degol 2016).

Structural/institutional characteristics, such as school size or urban versus rural location, tend to show no relationship with students' psychological well-being (Anderman 2002).

Students' Health Behaviors

Schools are a popular area for health promotion among children and adolescents, as they can target a large population in an efficient manner. Selected aspects of the school environment have been linked with substance use, eating habits, and levels of physical activity. Lower rates of *substance use* are found in schools with higher educational attainment and attendance than would be expected from the social profile of the students, although the mechanisms that explain this result have not yet been assessed (Bonell et al. 2013). Studies on restrictive school policies (such as a smoking ban) showed mixed associations with substance use, probably indicating the difficulties that accompany putting such rules into practice (Bonell et al. 2013). In line with this, higher numbers of unobservable and unsupervised places in and around schools are associated with higher substance use (Kumar et al. 2008). In general, associations of the school environment with substance use tend to be small or very small because most substance use occurs outside the school.

A review by Morton et al. (2016) indicates that a larger total campus size is associated with higher levels of *physical activity* at school. In contrast, availability of physical activity facilities, such as baseball fields or sports equipment, was not consistently related to higher physical activity, thus indicating that not all available opportunities are frequently used. Regarding teacher behavior, support for student autonomy (e.g., provision of choice), a mastery-oriented motivational climate, and, in part, physical activity promoting teaching behaviors were related with higher levels of physical activity among the students. Studies on schools' policies about "intramural versus interscholastic sports participation" indicated that intramural sports were consistently associated with more physical activity, whereas interscholastic sports showed no association.

Studies addressing school effects on students' healthy *eating* have found no significant school-level effects of the availability of healthy/unhealthy food on eating habits after controlling for student-level characteristics. However, there is some evidence for an independent statistical effect of school organization factors related to food choice (e.g., quality of information provision, related campaigns) which explained up to 12% of the variance of students' food choices (Townsend and Foster 2013).

Teacher Stress and Burnout

A positive teacher-rated school climate has been consistently linked to lower levels of stress, lower burnout scores, and lower attrition among teachers (McGiboney 2016). For example, teachers who report that they openly discuss issues of teaching quality with their colleagues and who perceive low levels of competitiveness between staff members report lower levels of burnout (Lim and Eo 2014). Teachers' negative perceptions of their students (e.g., low motivation), of the teacher-student relationships, and of the school administration (e.g., failure to set clear standards) have also been found to correlate with higher burnout scores (Grayson and Alvarez 2008). A meta-analysis by Aloe et al. (2014) found that high levels of student misbehavior are related to higher teacher burnout with mean

correlations varying between $r = 0.31$ and 0.44 . Associations of student problem behavior with teacher burnout tended to be stronger in younger and female as compared to male teachers.

Up to now, the causal role that the school climate plays in regard to teacher burnouts has been difficult to evaluate as studies are lacking that test the associations between the two variables either experimentally or longitudinally with cross-lagged analyses.

Intervention Research

Although the majority of work on the school environment has been correlational, a number of interventions have been developed for improving the school environment. Intervention effects from randomized controlled trials on academic achievement, behavior problems, psychological well-being, or other variables can provide more compelling evidence for a causal link between school environment and student outcomes. For example, a randomized controlled intervention study aimed at enhancing teachers' capacity to create a caring, well-managed classroom environment (the Responsive Classroom approach) showed that the use of responsive classroom practices mediated the effect of treatment assignment on academic achievement (Rimm-Kaufman et al. 2014). Nonetheless, similar to other studies, the size of the observed intervention effect tended to be small. Most intervention studies tried to change more than one aspect of the school environment, and many of them combined attempts to change the school environment with student-focused interventions (e.g., training of life-skills), thus precluding the identification of causal relations between individual aspects of the school environment and student outcomes.

Relating Genetic Dispositions and the School Environment

The View of Evolutionary Psychology on the School Environment

Schools are a relatively new cultural innovation, as places of active teaching did not exist in traditional hunter/gathering societies. The oldest

known classroom and pedagogical materials were found in Mesopotamia from the third millennium before the current era (Lancy 2016). There is some controversy whether active teaching has been relatively uncommon in our species' history and whether children have traditionally acquired their culture only through "self-guided learning" (e.g., observation, imitation) or whether there were some formal teaching processes through demonstration, intervention, and collaboration of experienced adults because complex skills are difficult to learn via self-guided learning. As the human mind and behavior have been shaped by natural selection for life in the hunting/gathering groups of our ancestors, we are not genetically prepared for today's typical school environment, i.e., sitting in classrooms with same-age peers, seated in chairs or at tables while performing "seatwork," or listening to instruction from a teacher (Bjorklund and Bering 2002). The misfit between evolved learning (and evolved learning contexts) and the modern-day demands of formal schooling (and characteristics of the present school environment) may cause common problems, such as lack of students' motivation or restless behavior in the classroom (Bjorklund and Bering 2002; Gray 2011).

Based on our phylogenetic history and data from extant traditional societies, Gray (2011) argued that an ideal educational environment would, for example, permit unlimited free time and an abundance of space in which to play and explore, provide opportunities for interacting with children of all ages, and allow freedom of expression and debate of any idea. A few schools that have adopted such a traditional approach to pedagogy found positive effects on students, in particular with regard to their motivation (e.g., Gray 2011). In contrast, other proponents of evolutionary psychology have explicitly stated that this theoretical approach should not be taken in order to adopt a "back-to-nature" approach to schooling (Bjorklund and Bering 2002), as socializing with one's peers and discovery-based experiential learning may not be beneficial for mastering abstract, evolutionarily novel information. Thus, teacher-directed instruction should be most effective when acquiring evolutionarily novel concepts

and skills that are remote from the folk domains of knowledge (e.g., solving linear algebra problems), and the goal is oriented toward acquiring knowledge for its own sake (Geary and Berch 2016). This view is consistent with empirical studies showing that sufficient external guidance is needed for effective learning, in particular if there is no prior student knowledge on the given content (Kirschner et al. 2006).

Up to now, evolutionary theory and evolutionary psychology did not play an important role for designing the school environment, as the basic assumptions on the evolution of species are very general, and as some debates (e.g., on direct instruction vs. experience-based learning; Kirschner et al. 2006) and concepts about learning environments had already come up independently of evolutionary psychology. For example, starting from 1907, Montessori education practices included mixed-age classrooms, students' choice of activity (from a prescribed range of options), and discovery-based learning.

Gene-Environment Correlations and Interactions

While evolutionary psychology has stated theoretical assumptions on genetic dispositions that affect learning of today's students, behavior-genetic and molecular-genetic studies have provided some empirical data on the role that genetic factors play within teaching and learning.

Genetic effects have been found on many aspects of the family environment as parents create a family environment that fits their own and their children's genetic disposition and as parents react to behavioral manifestations of the genes of their children (gene-environment correlations). In contrast, fewer genetic effects on the school environment could be expected as this environment is not child-specific. Nonetheless, genetic effects come into play when particular schools are actively chosen by the parents and/or children, when dyadic aspects of the school environment are assessed (e.g., teacher warmth toward the individual child), and when the individual perception of the school environment, rather than the objective environment, is analyzed. Up to now, very few studies have tested genetic effects on the

school environment. The behavior-genetic study by Brendgen et al. (2011) did not find an effect of student's genotypes on teacher ratings of his or her relationship with the individual student. Thus, teachers may try to show rather similar behavior (e.g., warmth, openness of communication) toward all students, regardless of their genetic dispositions. In contrast, Coon et al. (1993) found that associations of boys' academic achievement with attending a private school and with students' and parents' perceptions of competitiveness of the school environment were, in part, genetically mediated.

A number of studies on the school environment have identified gene $\times$ environment interaction effects. The biological sensitivity to context model suggests that variation in susceptibility to environmental influence has been maintained by natural selection because this variation promotes success and failure in different ecological contexts. While focusing on the school environment, Essex et al. (2011) showed that biological sensitivity to context moderated the effects of the early teacher-child relationship on the development of mental health by adolescence: The association of the teacher-child relationship with adolescent mental health was stronger for more reactive children. Differential sensitivity to context is associated with variations in dopaminergic genes. A study showed that the size of associations of student-reported teacher-student affiliation with parental reports on school engagement, and of associations between students' dissatisfaction with their teacher and rule-breaking behavior, was moderated by the dopamine transporter DAT1 and the dopamine receptor DRD4 genes, respectively (De Laet et al. 2016).

Some behavior-genetic studies addressed whether the size of genetic influences on student outcomes varies by the quality of the school environment. Stronger genetic influences on reading comprehension were found in the case of lower school-level SES (Hart et al. 2014), probably indicating that poorer school environments are less capable of compensating for the effects of less than optimal genetic achievement-related dispositions. In contrast, heritability estimates of aggression levels and levels of other forms of

externalizing problem behaviors were found to be higher in better school environments, such as those characterized by programs aimed at reducing violence (Boutwell 2010). While many students show some externalizing behaviors irrespectively of their genetic disposition in poorer school environments (e.g., because of social learning or peer pressure), these behaviors are more specific to students with genetic risks in the better schools.

Conclusion

The school environment is an important developmental context for children and adolescents which affects not only academic skills but also the development of social behavior, health behavior, and psychological well-being. Interventions aimed at improving the school environment have been shown to promote student development, although most effects tend to be small. These interventions should not only strive to improve the school environment but also the interplay with other environments, such as parental involvement in schooling (home-school linkage) and school-community linkages (e.g., provision of community service learning opportunities). Given the heterogeneity in definitions of the school environment and related aspects, in the proposed dimensional structure, and in the dimensions assessed with individual instruments, more unifying concepts are needed that increase the comparability of results across studies. Because students, parents, and teachers tend to perceive the school environment differently, it is recommended that researchers collect data from more than one source. As the quality of the school environment may vary by characteristics of the students' families (due to selection effects) and the neighborhood, careful research designs are needed that control for these confounding influences when searching for school effects. Given the possibility of bidirectional associations between aspects of the (perceived) school environment and student's feelings and behaviors, more experimental and cross-lagged longitudinal studies are needed for identifying the direction of effects. More

behavior-genetic and molecular-genetic research is also needed for getting a differentiated picture on the interplay of genetic dispositions with the aspects of the school environment.

While research on the school environment has been conducted based on a larger number of theoretical approaches (such as the Bronfenbrenner's bioecological model; Bronfenbrenner 2001), evolutionary psychology has not yet played an important role in that field. In order to gain importance, evolutionary educational psychology would have to provide more specific, testable hypotheses on the school environment and on environmental effects that go beyond common assumptions from other theoretical approaches. For example, the discussions on effective forms of learning (Geary and Berch 2016) could inspire systematic research that tests differential effects of teaching/learning strategies (direct instruction vs. discovery-based learning) for different kinds of materials and different groups of students.

Definition

The scientific study of morality has increasingly revealed its underlying psychological processes and features.

Introduction

Presently, there is no unified definition of morality (Krebs 2011). From a lay perspective, morality is

one's sense of the difference between right and wrong. It is a system of personal attitudes and beliefs about what actions are socially permissible, which behaviors should be morally condemned, and what degree of punishment is appropriate for various social transgressions; it is a collection of conventional rules that guide how individuals navigate and solve ethical dilemmas. In lieu of offering definitions of morality, current scientific research on morality attempts to identify the underlying psychology of moral intuitions by organizing aspects of morality into universal processes or features (Graham et al. 2013; Haidt and Joseph 2004); identifying the evolved, mechanistic design of moral cognitions and behaviors (e.g., Baumard 2010; Asao & Buss. 2016; DeScioli and Kurzban 2009; Kurzban et al. 2012); and detailing the neurobiological, computational, and social cognitive mechanisms of moral judgment and decision-making (Cosmides and Tooby 1996, 2006; Tooby and Cosmides 2010; Tooby et al. 2006; Gigerenzer 2008; Greene 2004). Collectively, this research has led to the development of several prominent theories of morality (Cosmides and Tooby 1996, 2006; DeScioli and Kurzban 2009; Mikhail 2007; Graham et al. 2013) as well as several relatively younger theories and ideas that elaborate on earlier models (Baumard et al. 2013; Asao and Buss 2016; Marczyk 2015). However, each is guided by the same underlying philosophy: morality is housed within a physical entity of the natural world (i.e., the brain) and can therefore be studied as a product of natural events.

The scientific method has been integral in identifying the processes and component features of natural phenomena within various areas of human inquiry (e.g., physics, biology, chemistry, psychology). In turn, this work has facilitated the development of technologies and ideas that have fundamentally shaped human societies. Using the scientific method to likewise examine the psychological structure and function of morality promises to reveal the underlying principles and processes of moral intuition and judgment. Current evidence suggests that morality can be understood as the result of biological processes and neurocognitive decision-making rules (Cosmides and Tooby 1996, 2006; Greene 2004; Gigerenzer

2008) whose design and development has been fundamentally shaped by natural selection (DeScioli and Kurzban 2009) and refined by experiences (Graham et al. 2013; Mikhail 2007). A complete scientific understanding of the structure and function of this moral machinery will be valuable insofar as it has the potential to inform ways of optimizing various features of modern human life that have traditionally been developed from folk understandings of morality, such as law (e.g., Cosmides and Tooby 2006; Stake, 2016 resource distribution (e.g., Greene 2014), values (e.g., Harris 2011), and treatment of social deviance (e.g., Kurzban et al. 2010; Glenn et al. 2009).

This section reviews current literature on the scientific study of morality. Given the complexity of this topic, a more exhaustive and detailed account of extant literature is forgone and may be found elsewhere (see Krebs 2011). Instead, several current scientific theories of morality are summarized and the practical applications of these ideas are discussed. To this end, this entry serves as a primer for those who are interested in contemporary scientific research on human morality.

Computational Heuristic Models

Several theorists detail computational heuristic models of morality (Cosmides and Tooby 2006; Gigerenzer 2008). Generally, these models outline how complex networks of heuristic decision-making rules guide moral reasoning and how these cognitive mechanisms may have been shaped by natural selection to address recurrent adaptive issues. In this respect, these models may be considered the foundation of other contemporary theories of moral psychology insofar as they identify and elaborate on the cognitive machinery underlying human morality. Heuristics are “fast” (i.e., require little time) and “frugal” (i.e., require little information) solutions to complex problems. They comprise solutions that address problems quickly and efficiently, but with potential for error, and are currently understood to be the building blocks of a heritable, modular psychology (Barrett and Kurzban 2006; Cosmides and Tooby 1996; Gigerenzer 2008). Moral heuristics

are therefore “rules of thumb” that underlie moral intuitions and judgment.

As an example, Tooby and Cosmides (2010) propose that adaptations for morality were born, in part, out of heuristics for coalitional living. Coalitional living is particularly complex in humans compared to other species and involves environmentally and socially responsive decision-making rules that guide how individuals form and maintain alliances, recruit allies, evaluate those allies, and motivate those allies into taking actions that are beneficial to the individual. These features of coalitional living are accompanied by unique adaptive challenges such as dealing with free-riders, negotiating social dominance hierarchies, distributing resources, coordinating group effort, and mapping alliance networks. They argue that the evolution of language, negotiation, and situation evaluation, in conjunction with adaptations to coalitional living, allowed for dynamically complex social games and thereby introduced novel adaptive issues (i.e., second-order moral games), and selection pressures (e.g., exploitation) from which moral heuristics evolved. Several lines of research support and elaborate on computational heuristic models, including several contemporary theories (see Asao and Buss 2016; DeScioli and Kurzban 2009, 2013; Greene 2004; Marczyk 2015; Mikhail 2007).

Moral Condemnation by Third Parties

DeScioli and Kurzban (2009, 2013) highlight the importance of third-party condemnation in understanding the design of evolved moral psychology. Whereas other evolutionary accounts of morality have focused on kin selection and reciprocal altruism as key pathways in the evolution of morality (e.g., de Waal 1996; Wright 1994); they propose the idea that adaptations underlying moral judgment function to strategically levy and avoid third-party condemnation. They differentiate between two subsystems of moral cognition: moral conscience and moral condemnation. Moral conscience refers to adaptations that regulate one’s own moral behavior whereas moral condemnation refers to adaptations that specialize

in judging another’s moral behavior. They use models of three-player games to demonstrate how actors (player 1) may perpetrate moral violations against victims (player 2) and be condemned for these behaviors by third parties (players 3+). Third-party condemners face the problems of detecting, judging, and punishing these violations while recruiting others’ support and avoiding counteraccusation (i.e., becoming targets of moral judgment). This condemnation thereby presents a different set of problems for actors who must weigh potential costs (e.g., victim revenge; third-party sanctions) and benefits when choosing to perform certain actions (i.e., moral conscience). Likewise, second parties should be expected to have evolved adaptations for avoiding costs (e.g., exploitation) and recruiting help from third-party condemners.

This view is consistent with computational heuristic models of morality (e.g., Tooby and Cosmides 2010) and has received support in subsequent studies. For example, DeScioli et al. (2011) found that people are more willing to take money from another person by omission than by commission when threatened by third-party punishment. This suggests that omission is a strategy for reducing the probability of third-party condemnation and punishment. Kurzban et al. (2012) also present evidence that the heuristics underlying moral judgment cannot be entirely explained by kin selection, reciprocity, or other altruism theories. Instead, they argue that adaptations for altruism (i.e., kin selection and reciprocity) and moral judgment are separate systems, and can, at times, be in opposition. Their evidence supports the idea that moral judgment is impartial (i.e., activated in response to an individual’s behavior rather than the outcome of that behavior) (DeScioli and Kurzban 2009). Indeed, impartial moral judgment based on behavior rather than an individual’s identity permits third-party condemners to change which parties (i.e., actors versus victims) they support depending on the potential costs and benefits of choosing one side over the other (DeScioli and Kurzban 2013). This suggests that humans may possess cognitive adaptations that motivate vigilance of moral disagreement (e.g., belief systems and development of

shared moral commitments) which allow individuals to adaptively prevent problems of coordination (i.e., increased partisan conflict and fight costs from siding with others based on preexisting relationships) and exploitation (i.e., empowering individuals to be able to exploit others).

Tripartite Theory of Machiavellian Morality

The tripartite theory of Machiavellian morality (Asao and Buss 2016) expands the moral condemnation and moral conscience distinction (DeScioli and Kurzban 2009) to include a third classification: moral influence. Under this conceptualization, moral judgment, moral influence, and moral conscience are functionally discrete collections of adaptations which strategically guide moral decision-making. Moral judgment adaptations allow an individual to identify whether a conspecific affords either a net cost (i.e., is exploitative) or a net benefit (i.e., is prosocial) to one's inclusive fitness. Moral influence consists of heuristics which evolved to efficiently and cost-effectively alter another's behavior so as to be less costly and more beneficial to one's fitness. Moral conscience heuristics evolved as counteradaptations to others' moral judgment and influence mechanisms, and thereby motivate an individual to avoid fitness consequences that arise from them.

The Evolution of Fairness by Partner Choice

Baumard et al. (2013) present a theory that elaborates on how partner choice may have been a key selective pressure from which fairness, a key feature of morality, evolved. Their theory rests on conclusions from game theory and models of mutualism which show that mutually beneficial cooperative exchanges permit individuals to accrue benefits that would otherwise be unavailable through solitary effort. Given these advantages, individuals are motivated to attract and invest in allies with whom cooperation will produce a better quality of life. However, because

people differ in their opinion of how mutually accrued resources should be ideally distributed, individuals should be selective about with whom they cooperate. Therefore individuals whose cooperation provides a net benefit will be favored as partners over those whose cooperation provides fewer benefits (or inflicts costs). They contend that moral conscience, as developed by DeScioli and Kurzban (2009), evolved to regulate one's reputation as a cooperator. Individuals who successfully monitored their moral reputation as a reliable cooperator would have been more frequently chosen for mutually beneficial exchanges, and therefore would have experienced greater reproductive success.

Moral Alliance Strategies Theory

Moral alliance strategies theory (Marczyk 2015) builds upon other work (Baumard et al. 2013; DeScioli and Kurzban 2009, 2013) by elaborating on why observable behavior, rather than identity, acts as input for moral cognitive mechanisms. Its central premise is that third-party condemners use actors' behavior to decide with whom to form alliances because these behaviors signal an actor's need for coalitional support. This need provides an opportunity for third parties to either invest in an alliance that is personally beneficially (i.e., provide support to the actor) or dissolve an alliance if it is too costly (i.e., condemn the actor). This implies that an actor's relational value influences third party condemnation decisions. Compared to other models, this theory reaches conclusions about the role of impartiality, proportionality, harm, omission, and moral praiseworthiness in moral cognition that are compatible with earlier models but offers additional insights into how these features may be influenced by an actor's relational value and shared interests.

Universal Moral Grammar

Universal moral grammar (Mikhail 2007) models human morality by drawing parallels between moral cognition and concepts used in the study

of linguistics. Like other theories, it emphasizes the importance of nativist intuition, modularity, and computational heuristics in moral judgment but elaborates these ideas using terminology endemic to Chomsky's program in linguistics. It rests on two fundamental arguments. First, the mind contains a moral grammar of complex and possibly domain-specific sets of rules, concepts, and principles that individuals apply to an infinite variety of moral acts and omissions. Second, this moral grammar is generated by the innate structure of the mind but is also developmentally shaped and refined by individual experiences.

Moral Foundations Theory

One of the more prolific contemporary theories of human morality is Jonathan Haidt's moral foundations theory (Graham et al. 2013). This theory posits that collections of universal and functionally distinct moral intuitions underlie individuals' moral judgments. These intuitions (i.e., foundations) precede moral reasoning, which is constructed after an intuitive judgment has already been made. Consistent with other perspectives, these foundations have been shaped by evolution by natural selection and are hypothesized to operate modularly. Each foundation describes a functionally distinct set of psychological modules which specialize in processing information that has been relevant to solving ancestrally recurrent adaptive problems inherent to group living. The care/harm foundation refers to psychological mechanisms which permit individuals to easily and automatically process cues of suffering in another individual. These mechanisms are hypothesized to have originated from mechanisms that motivate kin and reciprocal altruism and are sensitive to signs of distress and neediness that trigger feelings of compassion for victims. The fairness/cheating foundation comprises heuristics for identifying and reacting to evidence of cheating within nonzero-sum cooperative exchanges and relationships. In any social interaction, individuals attempting to establish a mutualistic exchange of resources with another individual may be cheated out of those resources. Individuals have therefore evolved mechanisms for identifying and judging

trustworthiness in cooperative interaction to avoid exploitation. The loyalty/betrayal foundation entails adaptations which facilitate in-group loyalty and condemn in-group betrayal, thereby increasing individual fitness via enhanced cohesion and effectiveness of the groups to which an individual belongs. The authority/subversion foundation consists of modules which permit individuals to effectively navigate social dominance hierarchies (e.g., via obedience and deference), thereby facilitating the formation of useful social alliances that provide material and reproductive benefits. The sanctity/degradation foundation includes modules that function as a "behavioral immune system" which motivates avoidance of stimuli that signal actual or moral pathogen risk (e.g., immigrants, sexual promiscuity). Each of these foundations is hypothesized to underlie cross-cultural variation in moral judgment and practices and give rise to these variations insofar as they supply the initial blueprint from which culturally nuanced variations in moral practices are subsequently developed and refined.

Conclusion

In a recent news article, Jonathan Haidt and Steven Pinker (2016, para. 13) explain the importance of a scientific understanding of morality:

Recent discoveries in moral psychology [reveal that]... many ethical convictions are underpinned by strongly felt intuitions that some action is inherently good or bad. Sometimes those intuitions can be justified by philosophical reflection and analysis. But sometimes they can be debunked and shown to be indefensible gut reactions, without moral warrant. Historical examples include outrage over heresy, blasphemy, and *lèse-majesté*, revulsion against homosexuality and racial mixing, squeamishness about medical advances like vaccination and blood transfusions, callousness toward slaves and animals, and indifference or hatred toward foreigners. Any news reader will confirm that some of these historical examples are all too modern.

Psychology, neuroscience, and evolutionary biology, though they cannot by themselves debunk moral intuitions, are highly relevant to evaluating them, since our naive intuitions about the ethical warrant of our gut feelings might themselves be gut feelings and cannot be taken at face value.

This passage highlights the advantages of deconstructing human moral psychology using

theoretical and methodological ideas from other sciences (i.e., neuroscience and evolutionary biology) whose work has fundamentally shaped our understanding of how humans process information, respond to their environment, and respond to each other. The theories of morality outlined above have been applied in understanding various social issues, including mental illness (Glenn et al. 2009), procedural fairness (Bøggild, and Petersen 2016), law (Cosmides and Tooby 2006), illicit drug use (Kurzban et al. 2010), and moral aggression (Benavidez et al. 2016). These types of practical applications of the science of morality promise to expand descriptive understandings of human morality and may have profound implications for the way that humans deal with moral transgressions. In the words of Sam Harris (2014, para 31):

We should admit that a person is unlucky to be given the genes and life experience that doom him to psychopathy. Again, that doesn't mean we can't lock him up. But hating him is not rational, given a complete understanding of how he came to be who he is. Natural, yes; rational, no. Feeling compassion for him could be rational, however—in the same way that we could feel compassion for the six-year-old boy who was destined to become Jeffrey Dahmer. And while you [may] scoff at “medicalizing” human evil, a complete understanding of the brain would do just that. Punishment is an extraordinarily blunt instrument. We need it because we understand so little about the brain, and our ability to influence it is limited. However, imagine that two hundred years in the future we really know what makes a person tick; procrustean punishments won't make practical sense, and they won't make moral sense either.

Science and Religion Compatibility

Christopher Starratt and Gerene Starratt
Barry University, Miami, FL, USA

Definition

Science and religion are two fundamental ways that we have of understanding ourselves and the universe

within which we exist. Both science and religion assert authority in the world. That is, both have – and utilize – “the power to influence or command thought, opinion, or behavior” (Merriam-Webster) in their respective areas of purview.

Science is the systematic study of the physical and natural world.

Religion is defined in a number of ways. For the purpose of this discussion, we will define religion as a shared system of beliefs, moral code, faith, and worship, with a focus on a god or similar supernatural forces. It is relevant to highlight the distinction between the *practice* of religion as the perspectives and actions of groups of people in regard to their faith (i.e., praxis) and the *tenets* of a particular faith (i.e., theology). While the *practice* of faith can be studied using quantitative and qualitative research methods, the *tenets* of faith are difficult, if not impossible, to investigate empirically, as they are not bound by the laws of the physical and natural world.

Science and religion compatibility refers to the degree to which beliefs about science have been viewed as being consistent – or inconsistent – with religious views and practices and the degree to which beliefs about religion may be consistent or inconsistent with the tenets and practices of science.

Introduction

The relationship between Western science and religion is one that has been discussed and debated among European scholars at least since the seventeenth century, which is when the scientific approach began to emerge, and be perceived, as a legitimate method for understanding the world in which we live (Barbour 1997). This relationship continues to be an active area of scholarly interest, as demonstrated by the number of academic journal articles being published on the topic. A search of the JSTOR digital archive of academic works that were published in English between January 2000 and August 2018 using the keywords *science* and *religion* yielded 25,453 entries. In fact, the convergence and divergence of science and religion is a topic of interest across

all three of the major monotheistic religions. Using the same search criteria as above with the keywords *Christianity* and *science* yielded 5,485 articles, *Islam* and *science* yielded 5,391 articles, and *Judaism* and *science* yielded 1,418 articles. The purpose of this work is to provide a general framework for understanding the intersection between science and religion in modern Western thought with reference to some of the more notable people, places, and organizations associated with this topic.

Perspectives, History, Studies, and Resources

One way to achieve a sense of the relationship between science and religion is to assess the perceptions of individuals. One's perception, of course, will be influenced by the respective roles that science and religion serve in the life of that individual. Perhaps the best starting point is to describe the ways in which taxonomies or categorization strategies have been used to facilitate understanding of the various ways in which people think about/describe the relationship between science and religion. For example, in an investigation of the contemporary philosophical and educational literature, Yasari et al. (2013) synthesized a number of existing taxonomies and proposed an empirically based taxonomy focused upon people's views of the relationship between science and religion. These authors ultimately proposed and investigated seven views that they believe capture the main perspectives on the relationship between science and religion.

- Although some aspects of science and religion appear to conflict, it is difficult to understand the conflicts.
- When science and religion conflict, science is correct.
- When science and religion conflict, religion is correct.
- There is no conflict because science addresses questions of the physical universe, while religion addresses questions of ethics, values, and purpose.

- There is no conflict because science constructs knowledge through the scientific method and religion constructs knowledge through interpreting religious writings.
- Science and religion answer the same questions, so it is possible to combine them.
- Science and religion are both useful to understand life, so they are complementary.

These perspectives can inform the development of a list of major questions that underlie the discussion of the compatibility of science and religion. The most productive conversations tend to revolve around the following questions, many of which are rooted in the scholarly writings from the seventeenth century to today.

- How has the perception of the relationship between science and religion developed over time?
- What are some of the ways in which science and religion intersect?
- What are the conditions under which science and religion can operate or function in a compatible way?
- What are the events, conditions, and circumstances in which science and religion cannot be viewed as being compatible?
- To what degree do science and religion – respectively and together – help us to deepen our understanding about the truth of human nature?
- In what ways have empirical methods been used to study religion and spirituality?
- To what extent is the discussion about intellectual reasoning or moral reasoning?

In order to provide a broad perspective on science and religion compatibility, we address a sampling of these questions below.

How Has the Perception of the Relationship Between Science and Religion Developed Over Time?

Within Western thought, religion predates science. The advent of scientific methods of investigation during the sixteenth and seventeenth centuries began to change the way we think

about the world and our understanding of the world. During this period, there was no serious competition or conflict between what we consider today as science and religion. Early men of Western science (e.g., Kepler and Newton) were religious men who saw no inherent incompatibility between their religious beliefs and their systematic exploration of the natural world. They viewed science as a procedure that helped us understand the Creator.

For example, the study and writings of Rene Descartes during the first half of the sixteenth century represent a movement toward a greater distinction between natural and theological understanding of the world. Descartes proposed a dualistic representation of persons as having both a physical presence (body) and a nonphysical presence (mind/soul). One consequence of this philosophical perspective during his time was a justification for systematic study of the body. At that time, the body was viewed as the temple of the soul (i.e., the spiritual essence of the individual), which did not allow for the human body to be violated for any purpose, including study. Descartes' dualistic theory broached the idea that the soul could, in fact, be separated from the body at death, thus opening the door to the study of human anatomy without fear of violation of the soul. This idea of the possibility of separation of the essence of the person from the body also signaled an increasing bifurcation between study of the natural world and the spiritual world. Eventually science became increasingly reified as the source of knowledge about who, what, and why we are in the world, which had previously been the purview of religion. This elevation of science became a source of contention among religious thinkers.

More recently, the popular notion of irreconcilable differences between science and religion is most commonly exemplified by debates between the two groups that have been described as *atheist scientists* and *religious fundamentalists*. These debates often center on issues related to the nature of the creation of the universe and the establishment of human existence, especially questions regarding the authoritative sources of such facts. Scholars have suggested that, in some ways, this discussion has evolved as a debate over

knowledge and which group holds the greater authority over knowledge generation, dissemination, and validation. In contrast, among those who view science and religion as authorities of different aspects of human experience (e.g., understanding the *what* of the physical universe, compared to the *why* of human moral behavior), there is less conflict and greater room for cooperation and collaboration.

What Are Some Ways in Which Science and Religion Intersect?

Science and religion are both institutions with the shared goal of increasing our understanding of the human condition. However, science and religion have divergent premises, beliefs, and strategies that underlie and serve that goal. As noted above, it is sometimes said that science is about *how* humans came to be here, while religion is about *why* humans came to be here. Therefore, beliefs about the creation of the earth and the beginnings of human life on this planet represent an inherent point of intersection. As an example of divergent viewpoints, a creationist view holds that life was created by a single divine creator at a specific moment in time (e.g., Ham 1987). In contrast, an atheistic scientific view is that life on earth evolved through a purely biological process that is spurred by natural selection, sexual selection, and genetic mutation (e.g., Dawkins 1986). These two exclusionary views would represent a point of contention between beliefs in religion and science that are irreconcilable. Any number of views that fall at midpoints between these creation-evolution endpoints suggest that there exists at least the possibility that there are scenarios that would allow both to be true (e.g., Haisch 2006).

In What Ways Have Empirical Methods Been Used to Study Religion and Spirituality?

Both quantitative and qualitative methods have been used to study various aspects of religion and spirituality. Quantitative studies of religion have been conducted within both experimental and nonexperimental paradigms. The following provide examples of different types of studies that one might find in the academic literature across diverse disciplines.

- Psychology is the study of human behavior. Consequently, studies of religion as a *psychological* phenomenon might address questions such as the following.
 - What are the personal characteristics of individuals who choose to be religious?
 - What are health outcomes for individuals who practice a religion, compared to those who do not practice a religion?
- Sociology is the study of human relationships in society. Consequently, studies of religion as a *sociological* phenomenon (a social institution) address questions such as the following.
 - What is the relationship between religiosity and civic engagement?
 - Are health (or religious, or psychology) outcomes related to religious affiliation?
- In any discipline (e.g., psychology, sociology, social work, nursing, education) studies of religion or spirituality as an experiential phenomenon address questions such as the following.
 - How do people feel about talking about God with people of different religions?
 - What is the experience of health or social service practitioners who provide services that are antithetical to their religion?

Experimental studies that attempt to bridge the gap between science, religion, and spirituality attempt to apply the tools of the scientific method to the investigation of the nonphysical aspects of religion, faith, and spirituality. Some classic studies are noted here as examples of research questions and methodologies that have been employed. To our knowledge, no study has yielded findings that provide support for any metaphysical aspects of religion. However, it is also relevant to note that, according to the tenets of the scientific method, the inability to demonstrate a phenomenon under experimental conditions (i.e., a null finding) is not the same as evidence that the research hypothesis is not true. However, repeated null findings in studies that use rigorous methodology can cast doubt on a hypothesis. One of the major obstacles to the scientific study of metaphysics is, of course, that the tools of science are designed to study physical – not metaphysical – phenomena. The following are

representative examples of historical and contemporary studies of spirituality related to religion.

In a now classic study that has been come to be called the *21 Grams* study, MacDougall (1907) attempted to demonstrate the soul as an entity separate from the body by documenting the weight of the soul as it leaves the body upon death. MacDougall used the simple but effective method of comparing the weight of the live body (ostensibly with its soul) against the weight of the body immediately after death (ostensibly after the soul has left), imposing logically appropriate experimental controls. In the *21 Grams* study, MacDougall reported a change in weight of 21 grams following the death of one subject, surmising that the human soul weighs exactly that. However, a number of follow up studies failed to confirm these findings and the studies have been widely criticized over time (Park 2010).

Similarly, a number of studies have been conducted over the years regarding the impact of intercessory prayer. For example, Galton (1872) wrote about a study by a contemporary in which he also recorded his own musings about the statistical evidence regarding the efficacy of prayer. More recently, Harvard researchers (Benson et al. 2006) conducted a randomized control trial to study the efficacy of intercessory prayer. In addition, Hodge (2007) conducted a meta-analysis of a large number of investigations of intercessory prayer.

Despite a lack of findings in these particular empirical studies, they serve as examples of historical and continued attempts to bridge the gap between science and religion in an effort to better understand our experience of the world. In fact, religious and lay academics and scientists the world over are engaged in this discussion through sites and programs such as the Vatican Observatory (<http://www.vaticanobservatory.va/>) and the Smithsonian's Human Origins Initiative Broader Social Impacts Committee (<http://humanorigins.si.edu/>).

A Representative List of Resources with a Focus on Science and Religion

The following are examples of academic resources, academic journals, and academic

centers that focus on science and religion. The list is representative, not exhaustive.

Academic Resources with a Focus on Religion and Science Although studies on religion are prevalent in the journals of any number of academic disciplines (e.g., psychology, sociology, and education), the following are examples of academic resources devoted entirely to the study of the relationship between religion and science.

- Journal for the Scientific Study of Religion (Wiley; <https://onlinelibrary.wiley.com/journal/14685906>)
- Stanford Encyclopedia of Philosophy: Religion and Science (2017)
- Theology and Science (Center for Theology and the Natural Sciences; http://www.ctns.org/theology_science.html)

Academic Journals with a Focus on Religion that Publish Empirical (in addition to philosophical) Studies About Religion. This is not a comprehensive list.

- Journal of Religion and Health (Springer; <https://www.springer.com/public+health/journal/10943>)
- Journal of Contemporary Religion (Routledge/Taylor & Francis; <https://www.tandfonline.com/toc/cjcr20/33/1?nav=tocList>)
- Journal of Religion and Society (Creighton University; <http://moses.creighton.edu/JRS/>)

Academic Centers Centers for the study of science and religion exist around the world. This is a representative (not comprehensive) list.

- Center for Theology and the Natural Sciences (CTNS; <http://www.ctns.org/about.html>)
- Ian Ramsey Center (Oxford; <http://www.ianramseycentre.info/aboutus.html>)
- International Association for the Cognitive Science of Religion (http://www.iacsr.com/iacsr/CSR_Links.html): Includes a list of resources that includes Journals and Reviews, Centers and Websites, Programs, and Associations under the headings of both “Science and Religion” and “Science of Religion.”

- Society for the Scientific Study of Religion (SSSR; <http://www.sssrweb.org/About.cfm>)
- Smithsonian’s Human Origins Initiative Broader Social Impacts Committee (<http://humanorigins.si.edu/>)
- Templeton Foundation (<https://www.templeton.org/>)
- Vatican Observatory (<http://www.vaticanobservatory.va/>)
- Zygon Center for Religion and Science (Lutheran School of Theology at Chicago; <http://zygoncenter.org/resources/>)

Conclusion

Although the dialogue about the relationship between science and religion is larger than evolution, what we typically read in the press are stories of large and irreconcilable differences between a religious view of the origin of human life and a scientific view of the origin of human life. However, it is also possible to find scholarly and general writing in which theologians take a less literal approach to the Bible that easily accommodates an evolutionary theory of the origin and development of the universe, including humans’ place in that universe. Similarly, there are scientists who accede to the possibility of some divine action that cannot be explored using the scientific method. Stories of scientists’ rationalization of their work with their faith also abound (e.g., Consolmagno 2007) and add perspective to the discussion. Among some, there is optimism that ongoing dialogue can foster a richer and fuller understanding of the universe and our place in it.

Definition

The scope hypothesis proposes when a generalization is retrieved from semantic memory; episodic memories that are inconsistent with it should be retrieved in tandem to place boundary conditions on the scope of the generalization.

Introduction

The scope hypothesis asserts that the function of priming inconsistent episodes is to place boundary conditions on the scope of a semantic summary. An excellent package of speed and accuracy can be engineered into a decision system by jointly activating a trait summary and episodic memories that are inconsistent with it. Trait self-descriptiveness judgments should activate trait-inconsistent, but not trait-consistent, behavioral episodes. In the event that scope hypothesis is supported, one would expect that trait-inconsistent episodic memories are primed by retrieval of a trait summary from semantic memory.

Boundary Conditions on the Scope of Generalizations

To rely on semantic memory alone is to sacrifice accuracy for speed as trait summaries lack the resolution of an episodic memory. Although trait judgments have predictive validity, the behavior of an individual manifests a great deal of situation specificity (Funder 1995). Episodic memories are situation specificity incarnate. They are records of how particular people behaved in specific situations. A system engineered to retrieve, along with a generalization, episodes that place boundary conditions on its scope would achieve the best of both worlds: speed courtesy of semantic memory and accuracy courtesy of episodic memory.

Decision Context

The decision context should determine when boundary conditions are needed, and which kinds of episodes would be relevant. Because decisions regarding personality traits are not amenable to all-or-none answers, it would be reasonable to assume that the trait summary takes a

quasi-quantitative form. Thus, when the individual is asked if a certain trait describes them possible answers might be “usually,” “sometimes,” or “rarely.” Boundary conditions would be episodes in which the behavior did not meet the criteria for that trait. This should be true for any level the trait summary specifies, even “rarely.” This is because the decision context calls for a generalization about it; the function of activating episodes is to place boundary conditions on that generalization. The issue is, “How often is Person Y friendly, and under what conditions is she or he not?” The decision rule activated is designed to make a judgment about the trait being asked about, whether the question originates with another person or with the individual making the judgment.

Different decision rules are designed to retrieve different kinds of information from memory. The type of decision being made matters, because that determines which search engine gets activated, which will determine which array of memory systems gets searched. When asked to trait-categorize their own behavior, subjects should retrieve a trait summary and episodes inconsistent with the trait they are being asked about.

Research Studies on Scope Hypothesis

On the basis of the scope hypothesis, it was predicted that retrieving a trait summary to answer a described question would prime trait-inconsistent episodes, but not trait-consistent ones. The first experiment probed knowledge about one’s own traits, because it is fairly certain that the typical adult already has formed a database of trait summaries about themselves. The second experiment probed knowledge about another person’s traits, the subject’s mother, to see whether the same results pertain when trait summaries are lacking.

The Self-Study

It was examined whether accessing a trait summary about the self would prime trait-inconsistent episodes but not trait-consistent ones (Klein et al. 2001). Subjects were presented with a list of trait adjectives and asked to perform one of three tasks with them. The describe task asked subjects to

decide whether the stimulus trait describes them; the recall task asked subjects to retrieve a specific instance in which they manifested the stimulus trait; and the define task asked subjects to generate a definition for the stimulus trait. If the scope hypothesis is correct, then deciding whether a trait is self-descriptive will activate a summary representation and episodes inconsistent with the trait being asked about. Empirically, one should observe two things.

The results showed that deciding whether a trait describes oneself facilitates retrieval of trait-inconsistent episodes, which suggests that these judgments activate memories of behaviors inconsistent with the trait being judged (Klein et al. 2001). By contrast, there was no evidence that trait self-descriptiveness judgments facilitated retrieval of trait-consistent episodes. Based on the outcome of the experiment, it is inferred that decisions about whether a trait describes oneself do not activate trait-consistent behavioral memories. That trait-inconsistent, but not trait-consistent, episodic memories are primed by retrieval of a trait summary from semantic memory is just what one would expect if the scope hypothesis were correct.

The Mother Study

This study had two primary objectives; first, it aimed to extend the generality of the scope hypothesis by testing whether judgements about a well-known other also conform to its predictions and, second, to address the finding that activation of trait-inconsistent behaviors occurred regardless of whether the trait judged fell in the high, medium, or low self-descriptiveness categories. This finding can be accommodated within the scope hypothesis by assuming that trait knowledge about the self is represented in summary form across levels of trait self-descriptiveness. According to the model of mental representation of trait knowledge about others, one’s representation of a person’s traits varies with the amount of experience one has had with that person. If the amount of experience is not sufficient to support abstraction, then trait knowledge will be represented only at the level of behavioral memories. Trait judgments about the person, therefore, must be

based on inceptive behavioral memories, that is, on episodes. However, as the amount of experience becomes sufficiently large, trait knowledge is increasingly likely to be abstracted and represented in summary form.

The study results illustrated that for traits highly descriptive of one's mother, ones for which a summary should exist, trait-inconsistent episodes were primed, but trait-consistent ones were not. For traits only moderately descriptive of one's mother, ones for which there should be no summary, the opposite pattern was found. Trait-inconsistent episodes were not primed, but trait-consistent ones were.

The results of this study strongly support the scope hypothesis as they allow for comparisons in priming when trait summaries are present versus absent. When a decision is made by accessing a trait summary, search engines should simultaneously retrieve inconsistent episodes to provide information about the conditions under which the summary ceases to be useful. Thus, trait-inconsistent behaviors were primed when a decision about one's mother was made by accessing summary representations of her traits. But when summary representations were absent, they could play no role in decision-making. This explains why trait-inconsistent behaviors were not primed in the medium-descriptive condition. According to the scope hypothesis, when no generalization has been accessed during a decision task, there is no representation whose scope needs to be delimited.

Conclusion

It has been argued that generalizations from semantic memory allow speedy decisions, but at the cost of accuracy, whereas episodic memories provide accurate, situationally specific, information, but at the cost of speed. Nevertheless, both speed and accuracy can be engineered into a decision-making system, if the system is designed to retrieve both kinds of information in the right combination. A generalization is most useful when its scope is delimited, that is, when

it is accompanied by information specifying those situations in which it does not apply. Episodic memories that are inconsistent with the generalization can facilitate this function because they are broadband encodings of specific situations in which the generalization fails to predict the outcome. Interpretively, this task analysis constitutes the scope hypothesis; a decision rule needs a search engine that looks for summary information in semantic memory and on retrieving it and looks for episodic memories that are inconsistent with that summary, ones that place boundary conditions on the summary's scope.

Definition

Scott Atran is an anthropologist and psychologists whose area of study focuses on values, conflict

negotiation, and the evolutionary psychology of religion.

Introduction

Much of Scott Atran's work has focused on values, conflict negotiation, and the evolutionary psychology of religion. Most of his work combines two or more of these areas to produce theories with real-world applications. For example, he studied how individuals hold and react to value violations (Atran and Axelrod 2008), applied this theory by asking Zionists and Palestinians living in the West Bank how they would react to different peace offerings were they to be proposed (Ginges et al. 2007), and summarized his data to be used by international organizations (Pinker 2011). Other notable contributions include his work on transnational terrorism, where he argues that terrorist ideology stems from nepotism, not psychopathy, with findings drawn from field work internationally (Pinker 2011).

Sacred Values and Conflict Resolution

Sacred values are moral imperatives that drive behavior in the absence of any specific goal (Atran and Axelrod 2008). These values are frequently the reported cause of many international conflicts. This can be problematic, as holding sacred values is a largely irrational behavior, and many international peace efforts approach conflicts as if adversaries will always make the rational choice. This is demonstrated through the rhetoric used by US foreign policy, where they state policy decisions should be informed by taking into consideration the goals of both parties through the use of results-oriented planning (Atran and Axelrod 2008). Because of this, many attempts at peace are met with outrage not because the offer was unreasonable, but because the offer did not take into account the sacred values of the other side (Ginges et al. 2007).

These sacred values may be the product of recurrent evolutionary problems, specifically those problems that posed a long-term threat to our ancestors. If so, this would explain why they can override our short-term self-interest to the point that it can cause death (Atran and Axelrod 2008). One such evolutionary recurrent problem may be the presence of children, as this value appears sacred across most cultures. Seeing the health of one's children as a sacred value would have been a struggle shared across all ancestors and one that would have had strong selection pressure for it. Furthermore, the presence of sacred values on non-evolutionarily recurrent problems may be the result of a selection pressure to promote cooperation. For example, the presence of sacred forests may represent a collective resolve to resist the temporary, immediate benefit of firewood for a shared access to renewable resources.

Although there are some examples of potentially beneficial sacred values, other examples such as sacred honor display a sacrifice far greater than any potential payoff. For example, many instances of desire for revenge are held so deeply it can result in death of the individual seeking revenge. In these cases, had the individual lived, there still would have been no payoff to their actions from a resource standpoint. In these cases, it is likely that a sacred honor represents a collective, rather than individual payoff. For example, consistent willingness to avenge regardless of the cost can deter stronger, less committed enemies from engaging in combat as the potential cost for them may be far larger than the benefit. This, it is argued, is a likely reason for seemingly irrational conflict (Atran and Axelrod 2008; Ginges et al. 2007). Further evidence for this was demonstrated by Atran et al. (2007) where interviews with families of Palestinian suicide bombers showed less willingness to accept compensation for a family member's death as the amount of compensation increased. This means that the more money offered, the less likely they would be to accept the money. They said that willingness to accept large amounts of compensation points to a focus on materialism and a disregard for their sacred value.

Symbolic Concessions

All of this points to a strong need to appeal to each side's sacred values in order to come to a peaceful resolution. One way of doing this is through symbolic concessions. Symbolic concessions are gestures that are weighty to one or both parties involved, but may seem trivial to an outside source. Symbolic concessions are, more often than other forms of negotiation, a quick and peaceful way of coming to a resolution. A problem with these acts is that policymakers are rarely able to implement this strategy as they are unable to see the other side's sacred values as sacred (Atran and Axelrod 2008).

A major problem with ignoring the sacred values of either side in a negotiation is that it can lead to violent escalation in a short period of time. For example, a large number of international negotiations involve presenting one side with resource in response to asking for a concession. In many affairs this works fine, but if the concession violates the other side's sacred values, then the results are problematic. Ginges et al. (2007) interviewed multiple groups in the West Bank and Gaza asking individuals for their responses to multiple proposals. The participants actually responded with more outrage when offered material compensation for violation of a sacred value than if they were simply asked to give up their sacred value with no compensation.

A successful method of resolving these issues is to offer a symbolic concession rather than a material one. Symbolic concessions are displays of a willingness to give up one side's sacred values as a concession to the other side giving up their own. As both sides are giving up something they believe to be priceless, the offer appears to be balanced for both. An example of this can be found between Zionist leaders and Germany post-WWII (Lustick 2006). Israel was in dire need of economic support and knew it could receive much of what it needed from Germany as compensation for the destruction of property inflicted on European Jews. However, at that time a sacred value held by Israel was a public boycott of anything German, including potential aid. To overcome

this, German leadership declared to the world that Germany was aware of the untold suffering brought upon the Jews of Germany and elsewhere and that most German citizens held in contempt any who had participated in the genocide. This declaration functioned as a sacred concession, with Germany giving up what had previously been a sacred value of supporting Nazism, while the Jews gave up their sacred value of boycotting Germany. In this example, the sacred concession did not complete negotiations, but it opened the way for further negotiations and the allowance of resources to be transferred without the violation of sacred values.

Real-World Applications

Atran has addressed the UN Security Council on multiple occasions to advise on matters of violent extremism in international terrorism. Unlike most of the research on this topic, Atran approaches many of these extremists from a sympathetic viewpoint, allowing him to better understand their operations and motives. His main focus in these discussions is to demonstrate the impact of youth and social bonds in the presence and spread of terrorism.

While performing field research, Atran discovered that roughly three out of every four people who join ISIS or Al Qaeda outside of the Middle East do so through friends, with the fourth being recruited through family or travelers. A large reason for this is that the parents in groups of Muslim refugees refuse to discuss the problems going on in their homeland with their children, leading to intense desire from their children to understand. This leads to uninformed youth actively seeking out and, subsequently joining, extremist groups (Atran, as cited in Downey 2015).

The goal of these discussions is to reframe the perception of violent extremists from inhuman psychopaths to disgruntled youth desperately trying to find a place for themselves. Atran puts it best in his address to UN Security Council: "Violent extremism represents not the resurgence of traditional cultures, but their collapse, as young

people unmoored from millennial traditions flail about in search of a social identity. . . They radicalize to find a firm identity in a flattened world” (see Downey 2015, para. 12). In these groups, their primary sacred value is a need to belong, and any attempts at stopping them without first granting them sympathy violates these values, leading to subsequent retaliation and failure to negotiate. To prevent this, Atran presents three conditions that must be met before any resolution can be met.

First, Atran argues that to counter terrorist groups, the youth which may potentially join them must be offered something that makes them idolize “a life of significance through struggle and sacrifice in comradeship” (see Downey 2015, para. 18). The reason such a grand sounding offer must be presented is because this is what is being presented by terrorist groups. The youth that join these groups do so because they are offered a chance to be a part of something bigger than themselves. When you compare this to the many countries they are forced to flee to, where racism and institutional prejudice isolate and alienate these youth, it is clear why they join violent extremists (Atran, as cited in Downey 2015).

The second condition is that youth must be offered a positive personal dream with a solid chance of it being realized. Atran fails to offer direct suggestions for this condition other than critiques of current practices (Atran, as cited in Downey 2015). Although terrorist groups will recruit youth through appeals to moral crusades, governments frequently do no more than fan these flames. By providing outlets for youth who have a desire to be passionate, governments may be able to redirect some of the youth attracted to these groups.

The final condition presented by Atran is the need to allow youth to create their own local initiatives. By engaging youth in projects that provide meaningful ways to alter the world around them, governments will simultaneously be providing an outlet for the youth’s passion while allowing them to fix the local problems that may cause transitions to violent extremism. As the most frequent recruitment tool of radical

extremism is to elicit moral outrage over a shared negative circumstance (Atran, as cited in Downey 2015), allowing the youth to fix the negative circumstance would provide a solid solution.

Conclusion

Scott Atran has studied a wide range of topics with a focus on minimizing violence between groups. Starting with work on sacred values, Atran began to develop models of conflict negotiation rooted in the evolved psychology of humans. From here, he developed a model of sacred concessions that multiple international organizations have used to smooth out negotiations between conflicting sides. Finally, Atran is currently investigating details of terrorist groups from an anthropological perspective to better understand and inform international groups on how to peacefully resolve future hostile situations.

Search Time

[Search latency](#)

Definition

The search phase of foraging refers to movements or strategic waiting that increases an animal's chances of finding food, and *search time* is the interval between the onset of those activities and prey capture.

In ethological terms, searching is a part of the appetitive phase of a motivated behavior, such as seeking food, water, or a mate. With regard to predatory behavior, searching may involve active, directed movement within areas where prey have previously been encountered, waiting in ambush for prey, or increased movement within the predator's home range where prey *may* be present. Both endogenous (hunger) and exogenous (movement, sound) cues can elicit search behavior. Once a food item or source has been secured, the predator engages in handling and ingestion responses (*consummatory responses* in ethological terms).

The time spent searching for prey represents a cost to the forager in terms of energy spent, time

away from other survival and fitness relevant activities, and increased vulnerability to predation because the forager is away from refuge sites or is distracted. However, since food does not land in the lap of the forager, it must endure these costs. Adopting an optimal search strategy can outweigh the costs of foraging with the benefits of finding an adequate food source.

Search time varies by characteristics that are both inherent to the predator, such as species-typical foraging behaviors, and the environment in which it forages. Active search mode (referred to as cruising) involves maximizing coverage of a search area where prey are likely to occur during a given time period. Ambush searching involves remaining still in order to minimize detection by prey and maximize the ability to detect moving prey (Schoener 1971; Alpern et al. 2011). Search time will be influenced by which of the strategies is adopted or how they are used in combination while foraging. Foraging bats remain in active search mode and therefore allocate far less, if any, time to ambushing prey compared to vipers. In contrast to both, lions might spend considerable time traveling to areas where prey are likely to be encountered and then switch to stealth mode as prey searching becomes more targeted.

Learning impacts search time. The *search image*, a topic of ethological study, refers to a perceptual fine tuning that allows the predator to increase the likelihood of detecting prey. Acquiring a search image to prey that use cryptic coloration as a mechanism of defense is an example. Thus, perceptual learning may influence search time. The role of learning in search time is also integrated into *behavior systems theory* (Timberlake 1994). Behavior systems theory describes how learned responses interact with the mechanisms and processes of unconditioned, biologically essential responses involved in feeding, reproduction, and other adaptive behaviors. The feeding system involves different responses occurring on the continuum of locating and ingesting food. Predation can be divided into a sequence of modes, or motivational substates, which function to bring the predator closer to its prey. Feeding begins with a general search

mode, progresses to focal search, then to handling and consuming prey. If the predator is not satiated, it will return to focal search mode and then to either handling-consuming if new prey are secured, or to general search, depending on the immediate availability of additional food. General and focal search modes are both elements of total search time but are behaviorally distinct. For example, general search may involve moving and tracking the strength of olfactory cues and then transitioning to focal search responses such as visual tracking, running, and prey capture.

The effects of learning processes on search time have also been examined in instrumental conditioning procedures. As described in prey choice, concurrent chain reinforcement schedules are used to study how organisms allocate responses in proportion to available reinforcement. Two salient properties of reinforcement learning are the amount of work needed to acquire the reward and the delay to receiving the reward. Behavioral ecological models of optimal foraging encompass both of these properties, with search time relevant to the delay aspect: Longer delays to reward are analogous to increased search times during natural foraging situations. Williams and Fantino (1994) tested the relative roles of rate maximization of reinforcement and delay to reinforcement in pigeons and found that the animals were particularly responsive to conditioned reinforcers that signaled shorter waiting times for food. Thus, although food profitability is a crucial factor in optimality modeling (and in real feeding behavior), reducing the delay, and therefore search time, is also important.

As described in ► [prey choice](#), the optimal diet model

$$\frac{E_2}{h_1} > \frac{E_2}{h_2}$$

predicts that larger, more energy profitable (E) prey₁ will be chosen over prey₂ unless handling time h justifies reversing the preference. If

handling times are equal, the choice should always be the larger prey₁. However, if smaller prey₂ is encountered, the forager must compute whether it is worthwhile to pursue and consume the smaller prey or continue searching for a larger item. Search time can be integrated here as

$$\frac{E_2}{h_2} > \frac{E_1}{S_1 + h_1}$$

with S_1 representing the search time for the larger prey item. Thus, prey₂ should be chosen if:

$$S_1 > \frac{E_1 h_2}{E_2} - h_1$$

Search time is an important component of both behavioral ecological and psychological perspectives of feeding behavior. For behavior systems theory, the amount of time predators spend finding prey will be a function of behavioral, motivational, and perceptual constraints. Instrumental analogs to natural foraging behavior emphasize the relative contributions of rate maximization of reinforcement and delay reduction, with the latter emphasizing the saliency of anticipated search time in foraging decisions. Behavioral ecological models mathematically incorporate search time by factoring it in with other critical variables such as energetic profitability and handling time.

Sex discrimination against male.

Introduction

In 2003, David Benatar published an essay on a phenomenon he called the second sexism. It received harsh criticism in proposing

recognition about the existence of another sexism's facet, but this time against males. In 2012, David Benatar's book *The Second Sexism: Discrimination Against Men and Boys* was published, in which he abstracts this discussion, reinforces arguments, and presents more evidence of wrongful discrimination against males based on sex. The book exposes several situations where males are disadvantaged compared to women, such as, are more likely to military conscription, to be victims of violent crimes, to receive more frequently and intense corporal punishment, to their sexual assault be taken less seriously, to lose custody of their children in the context of divorce, and so on.

The Second Sexism

Sexism is defined by Benatar (2012) as a wrongful discrimination based on sex. Thus, the second sexism is another facet of sexism, whose primary victims of unfair discrimination are males. It presents sexism as a continuum composed of two facets and only one of its forms is taken seriously and studied; in other words, the second sexism is an unrecognized form of sexism. Benatar's position is that men and boys are victims of sexism, but this wrongful discrimination is not widely recognized as those against women. It endorses the existence and the seriousness of the first sexism (when females are the primary victims). However, there is a predominance of the scientific literature about the first sexism and a lack of knowledge and denial about the second sexism. It claims that discrimination against men undermines the fight against sexual discrimination in general. His first effort to systematize the second sexism (Benatar 2003) received objections mainly focused on cultural factors and in defense of the first sexism rather than the second sexism (e.g., Quinn and Tong 2003; Digby 2003). The main issues of his first essay and the second sexism's book remain without academic attention, particularly the implications about sex differences on the male disadvantages' explanations. Only cultural aspects were considered, but

to a lesser extent (Kelland 2014, 2015), even so Benatar (2015) considered these researches as an ideological opposition.

Sex Differences and Second Sexism

One of the central issues of the book is the claim that beliefs about men, based on the discussion of sex differences, allow us to understand and justify second sexism. Benatar enquires about the existence of a biological basis for the differences between the sexes and the extent, if any, of their influence. Although, he is ambiguous in considering the psychological differences between men and women to be appropriate. Sometimes the author assumes these differences, as when he endorses the statement that women tend to have smaller standard deviations in intelligence, but also fewer geniuses. In another moment, he minimizes it when he questions whether men are more aggressive than women. And finally, underestimates evidence of sex differences, for example, ignoring why men are predominantly the perpetrators of wrongful discrimination against men and women. The author usually recognizes the influences of biology in a general sense (e.g., environmental influences, nutrition) but underestimates or disregards sociobiology and evolutionary psychology contributions about the effects of evolution on human psychology and behavior. This ambiguous position reflects in his argument on the sex differences, so he recognizes that the basis for distinctions is primarily biological but accuses evolutionary psychologists of overestimating them.

Sociobiologists and evolutionary psychologists present empirical data on sex differences and similarities, provide an evolutionary account of sex selection, and present the psychological and behavioral consequences of different reproductive strategies of men and women. In this way, these contributions can facilitate the understanding of the issues raised. For instance, in presenting the beliefs about males, Benatar argues that commonly the lives of adult male

seem to be less valuable than adult female lives. It is because female lives are more important for procreative efficiency and population survival than the male lives. While a man has the potential to fertilize a large number of women, ensuring continuity of the population, a woman can only become pregnant and have a baby approximately once a year, regardless of the number of partners available. Despite of the capacity of societies to survive with higher rates of female mortality or the individual desire to preserve the human species through reproduction, it has been in the evolutionary history of our species that attitudes toward the male and female lives had been constituted. The preservation of women's and children's lives is a priority over the preservation of adult male lives because it increases the chances of a population's survival. Therefore, in the face of a disaster, men, to protect these other lives, are most likely to be sacrificed or put at risk. This factor, as well as intrasexual competition, helps to understand why there is predominance in male victimization by other males in genocides. Intrasexual competition seems to have the function of stimulating the search for resources and mates rather than the complete population's genocide. Intrasexual competition helps to understand why violence against men is more common and socially accepted. The intrasexual competitiveness of males, as part of evolution, influences human behavior and psychology. That's because while women have a high degree of certainty that their descendants are theirs, men can never have the same degree of certainty. In this competition, some traits are more adaptable for the male. According to Buss and Shackelford (2008) women want good genes indicators, good investment indicators, good parenting indicators, and good partner indicators, it all from the same men, only limited to their own mate value. Thus, there is a desired pattern that involves features such as masculinity, muscularity, "confrontativeness" (Gangestad et al. 2007), current and potential acquisition of resources (Buss and Schmitt 1993) among others.

Conclusion

The second sexism proposes the existence of wrongfully discrimination against men and boys, unfair disadvantages that male experiences for the fact of being a male. Rigorous arguments and empirical data are presented to support a second sexism, situations in which males are the primary victims of unfair discrimination. Even if evolutionary mechanisms explain the devaluation of male lives, this does not justify doing so, since there are no relevant sex differences to justify an intrinsic value of one life over another. Also, one may choose to morally reject the view that boys and men should be more resilient, aggressive, assertive, sexually assertive, and greedy than women. However, the selected adaptive differences remain. The more valuable lives of women and children compared to the lives of males because of the importance for population survival. Males' vulnerability in suffering violence is due, among other things, to competition for mate and resources, and the acquisition of desirable characteristics such as masculinity and "confrontativeness." It is necessary to expand the knowledge on the subject, considering the researches of evolutionary psychology and the extension of the influence of biological factors in extent of the second sexism.

Definition

A secondary sexual characteristic is defined as a sex-specific trait that appears at the onset of sexual maturity and plays a role in sexual selection but is not directly involved in, or essential for, the act of reproduction (Darwin 1871).

Introduction

In the animal kingdom, an extraordinary diversity of structures exists that cannot be explained by natural selection (Darwin 1871). Consider, for instance, the elaborate antlers in a male deer (Fig. 1a; family Cervidae; Emlen 2008) or the wonderfully extravagant feathers of the peacock (Fig. 1b; *Pavo cristatus*; Petrie et al., 1991). These remarkable structures, referred to as secondary sexual characteristics, are most commonly observed in males and are thought to have evolved by means of sexual selection (Andersson 1994). These sexual characteristics may be energetically costly to produce and maintain and may be conspicuous, potentially subjecting the bearer to an increased risk of predation (Andersson 1994). Moreover, the use of such structures as advanced “weaponry” during combat with rival males while striving for the attention of females can lead to

injury or, in extreme cases, even death (Miller 2013). This raises the question: if these characteristics are so costly, why have they evolved in the first place? In *The Descent of Man, and Selection in Relation to Sex* (1871), Charles Darwin laid the foundation for the two main theories on sexual selection that still persist to this day:

There are many other structures and instincts which must have been developed through sexual selection - such as the weapons of offence and the means of defence possessed by the males for fighting with and driving away their rivals - their courage and pugnacity - their ornaments of many kinds - their organs for producing vocal or instrumental music - and their glands for emitting odours; most of these latter structures serving only to allure or excite the female. (1st Edition, volume 1, p.p. 257–258)

In this seminal book, Darwin posits that secondary sexual characters may evolve either as “weapons” that enhance a male’s competitive ability in male-to-male competition for access to females or as “ornaments” that enhance a male’s attractiveness to females (Fig. 1a–d).

The Evolution of Sexual Characters as Weapons by Means of Male-Male Competition

In many species male-male competition is known to play a pivotal role during sexual selection. It is generally accepted that male-male competition can drive the evolution of secondary sexual characteristics by improving a male’s success in competition for mates with rival males (Darwin 1871; Miller 2013). Secondary characters involved in male-male competition can include songs, colors, ornaments, as well as characters involved in direct combat. In systems where males engage in fierce struggles for access to females, traits that enhance a male’s competitive success (either directly by overpowering rivals with weapons during combat or indirectly by deterring rivals with powerful songs or impressive displays) will also directly increase their chance of reproduction. Here, secondary sexual characteristics convey a clear fitness advantage, because the male with the most impressive song or most advanced weapon will chase away its rival and get the chance to mate

Secondary Sexual Characteristics, Fig. 1 Photographs showing secondary sexual characters: (a) a male red deer (*Cervus elaphus*) showing off its antlers (Source: Wageningen University), (b) a peacock (*Pavo cristatus*) presenting its extravagant tail (Source: Wageningen

with the female and produce offspring (Miller 2013). Theory predicts that such secondary sexually selected characters will evolve when the benefits of increased reproductive success outweigh the potential costs of producing and maintaining such structures, and an increasing body of literature on this topic indicates that male-male competition is indeed responsible for the striking diversity of weapons (i.e., antlers, horns, and tusks; Fig. 1a) in the animal kingdom (Emlen 2008; Miller 2013; Panhuis and Wilkinson 1999).

The Evolution of Secondary Sexual Characteristics as Ornaments by Means of Female Choice

Secondary sexual ornaments can also be selected because they facilitate female mate choice

(Andersson 1994). If females show a preference for a particular male character, then males having that character will have a greater fitness. Male ornaments are thought to have evolved in a variety of animal species, but the most famous examples come from birds, for instance, the extravagant plumage of male birds-of-paradise (family Paradisaeidae), the long tails of long-tailed widowbirds (*Euplectes prognus*; Andersson 1982), and, of course, the ornamented tail of peacocks (Petrie et al. 1991). There are two main hypotheses explaining the evolution of male ornaments by female choice:

- (i) Fisher's (1930) runaway model of sexual selection (also known as Fisher's "sexy son" hypothesis) proposes a correlation between the expression of a male trait (ornament) and female preference for that ornament.

Such genetic correlations between ornament and preference arise when females with a preference for a particular ornament mate with males that have that ornament, leading to the production of offspring that have both the genes for the ornament from the father and genes for the preference of the ornament from the mother (Fisher 1930). Fisher argued that, initially, a “primitive form” of the male trait might have evolved because it was favored by natural selection and that it subsequently evolved into an exaggerated ornament via a self-reinforcing runaway process of trait elaboration (while females simultaneously evolved an enhanced preference for that ornament) that continues until the fitness costs (e.g., reduced survival) of having that ornament outweighs the fitness benefit of increased reproductive success. Houde and Endler (1990) tested this hypothesis in natural populations of the Trinidadian guppy (*Poecilia reticulata*) that varied in the amount of orange coloration on males. They showed that in populations where males had a more pronounced orange coloration, the females also had a stronger preference for this trait, suggesting a genetic correlation between the male trait and female preference consistent with Fisher’s hypothesis (Houde and Endler 1990).

- (ii) Zahavi’s (1975) “handicap” hypothesis (also referred to as the “good genes” or “condition-dependent indicator” hypothesis) proposes that females choose males with exaggerated ornaments, because these represent a reliable indicator of the male’s genetic quality. The presence of a large elaborate ornament is costly and can severely impair a male’s chance of survival. The ability to survive despite bearing such a costly feature (or “handicap”) provides an honest signal of the condition of the male and, hence, the overall fitness of the male’s genotype (Zahavi 1975). Females that mate with males that have exaggerated ornaments will thus produce

offspring with a higher fitness, because they pass these “good male genes” on to their offspring. One of the most famous examples is the extraordinary tail of the male peafowl (*P. cristatus*). A study by Petrie et al. (1991) on a peafowl population from England shows that the number of eyespots of a peacock predicted its mating success, i.e., more eyespots significantly led to more matings. This increased mating success was attributed to female choice (rather than male-male competition), because females always chose from more than one male. Furthermore, offspring sired by males with more eyespots survived better, which supports the “good genes” theory (Petrie et al. 1991). Another classic study was done by Andersson (1982) on long-tailed widowbirds. Male widowbirds can have remarkably long tails: up to half a meter. Andersson experimentally modified the length of the tail: elongating the tail of some males and shortening it in others. Males with elongated tails attracted significantly more females than males with shortened tails (Andersson 1982). Moreover, males with shortened tails performed better at flying and, hence, presumably were better at escaping from predators, indicating that long tails represent a handicap to males (Andersson 1982). This suggests that female choice can lead to the evolution of costly male traits.

Conclusion

There are two main hypotheses explaining the evolution of secondary sexual characters by sexual selection. The first states that these characters have evolved as “weapons” to improve a male’s success in combat with rival males. The second hypothesis states that these characters have evolved as attractive “ornaments” by means of female’s choice.

Secure Attachment

Definition

Secure attachment denotes a flexible and balanced (“optimal”) organization of attachment behavior in relation to the caregiver, which is observable in these children’s ability to use their caregiver as a secure base from which to explore the environment freely when there are no signs of danger, and as a safe haven to turn to for comfort and protection when distressed. Secure attachment is reliably predicted by having a consistently available caregiver who is responding sensitively to the child’s signals, supporting the child’s exploration and providing comfort and protection when the child is distressed.

Introduction

John Bowlby, a British psychoanalyst and child psychiatrist (see ► [“John Bowlby: Pioneer of Attachment Theory”](#)), was unsatisfied with the explanations of attachment available at the time, which deemed children’s attachments to their caregivers a secondary result of other mechanisms, such as children’s drives and/or feeding (see ► [“Psychodynamic Foundations”](#)). Seeking an alternative explanation for the phenomenon of attachment, Bowlby founded attachment theory by drawing from multiple scientific traditions, most notably ethology, cybernetics, and cognitive theory (see ► [“Evolutionary Foundations of the Attachment System and Its Functions”](#)).

Specifically, Bowlby (1982) argued that humans come into the world endowed with an attachment behavioral system (and attachment behaviors), which function is to maintain proximity to caregivers and which was retained through

natural selection as it was associated with increased chances of survival against predators and other natural dangers (see ► [“Infant Survival”](#)). Thus, children (the weaker, smaller part) form attachment bonds to caregivers (the stronger, wiser part) who are sufficiently available and responding to children’s signals (not the other way around; see ► [“Offspring–Parent Attachment”](#)).

Bowlby, having to contest the theories of attachment available at the time, and formulate a new, scientifically based explanation for the phenomenon of attachment, devoted a great deal of effort into the normative aspects of attachment. Subsequently, although he believed that there are interindividual variations in the “quality” of children’s attachment, manifested in cognitive affective representations of self and others formed from the history of interactions with the caregivers (e.g., “internal working models” [IWMs]; see ► [“Individual Variations in Attachment”](#) and ► [“Evolutionary Foundations of the Attachment System and Its Functions”](#); Bowlby 1982), he did not get around to systematizing these variations. Lacking an empirical method for examining variation in the quality of attachment, he instead focused his efforts on the need for a continuously available and responsive caregiver and the negative effects following separations and or loss of caregivers, which were readily observable in the post-world war era (e.g., Bowlby 1982; Robertson and Bowlby 1952).

Attachment theory therefore owes much to his close collaborator Mary Ainsworth and her colleagues and students, most notably Mary Main, for the subsequent mapping of systematic individual differences in attachment quality and organization (Ainsworth et al. 1978; Main and Solomon 1990). Drawing on Bowlby’s ideas about the interaction between the attachment system and other behavioral systems, most notably the exploratory system, Ainsworth devised a semi-structured laboratory observation method, called the “strange situation procedure” (SSP), which enabled examination of the organization of behavior that infant toddlers (aged 12–18 months) strike between their attachment needs and those of exploration. That is, the quality of children’s

attachments to their caregivers cannot be indexed by any single behavior, but is rather seen in the organization of behavior in relation to the caregiver (see ► [“Individual Variations in Attachment”](#)).

Ainsworth and her colleagues discovered three organized patterns of attachment. The first pattern, secure attachment, which is considered the optimal organization of behavior (e.g., highest quality) and which is shown by about two thirds of children from low risk contexts, is discussed below (see ► [“Organized-Insecure Attachment”](#) for the other two organized patterns and ► [“Disorganized Attachment and Reactive Attachment Disorder”](#) for children who cannot maintain an organized strategy of attachment behavior and children showing profound difficulties forming attachments).

Secure Attachment

Behavioral description. What is meant by secure attachment, or “a secure organization of behavior,” is best described with the (varied) behavior these children show in the SSP, where their behavior is typically characterized by a flexible balance between attachment behavior and exploratory behavior. In the SSP, secure children typically use their caregiver as a secure base from which they explore the room and the play material in the initial pre-separation episodes. Their play is typically elaborate and complex, and they tend to check back and share their experiences with the caregiver, holding up toys, smiling and vocalizing, and often seeking to involve their caregiver in their play.

Upon the entry of the stranger, secure children show varying reactions, with some children retreating to their caregiver as a safe haven, whereas others are more immediately responsive to and interested in the stranger. Indeed, four sub-patterns of secure attachment have been identified (Ainsworth et al. 1978), possibly in part reflecting differences in temperament (Belsky and Rovine 1987; Vaughn et al. 2008). Indeed, whereas secure children at one extreme can be described as “happy with distance interaction,”

at the other extreme, some secure children can be described as “happy playing on the caregiver’s lap.” However, as long as they are allowed to be in close proximity with their caregiver, most secure children eventually accept interaction with the stranger.

When the caregiver leaves the child with the stranger during the first separation, secure children again show varying reactions, with some children being happy to play with the stranger or playing independently, some children becoming distressed after a while and showing aversive signaling behavior (crying, screaming), and other children immediately displaying signaling behavior and protesting the separation, calling for the caregiver to come back.

In the two reunions with the caregiver, particularly in the second reunion episode wherein the stress is typically more pronounced, secure children who have become distressed by the separation typically approach the caregiver and/or signal to the caregiver that they want proximity and/or comfort (proximity-seeking behavior). Importantly, secure children who have become distressed are successfully soothed by this contact, so that they can eventually go back to exploring the play material. They also show that they are effective in maintaining the contact with the caregiver for as long as they need in order for the attachment system to become inactive (contact-maintaining behavior). For example, secure children protest effectively if the caregiver should try to put the child down too soon (e.g., clinging to the caregiver, turning to make closer contact), prolonging the contact to get what they need. That is, they show an ability to use the caregiver as a safe haven when their attachment system is activated. Secure children who have not become particularly distressed by the short separations tend to greet the caregiver happily, try to involve the caregiver in play, and share their experiences with the play material. That is, and addressing a common misconception, children do not have to cry following short separations (in the SSP, maximum 3 min) in order to be judged securely attached.

Secure children typically do not show marked avoidant behavior, such as turning away from and

ignoring the caregiver for a substantial amount of time in the reunion episodes (a hallmark of avoidant attachment). Moreover, secure children show limited ambivalence and resistance in relation to the caregiver in the reunion episodes (a hallmark of resistant attachment), although some secure children, particularly if distressed, can show some initial resistance. Secure children also tend to show a marked specificity in their preference for the caregiver. Even if they can be partly soothed by the stranger for a while, the caregiver is much more effective in soothing the child. Moreover, secure children who have not been particularly distressed by the separations and have played with the stranger during the separation episodes tend to interact more with and share more emotions with the caregiver than the stranger. Importantly, this description of variations in “specific” behaviors shown by secure children underscores the need to examine the “organization” or patterning of behavior and not focus solely on any individual behavior.

Predictors of secure attachment and developmental correlates. Ainsworth and colleagues found that secure children tend to have caregivers who, during the home observations, were sensitive to the children’s signals. That is, they perceived their children’s signals and responded to them in a timely and appropriate fashion. They both acted as a secure base, supporting children’s exploration, and as a safe haven, effectively comforting the children when distressed. The link between sensitivity and attachment has subsequently been supported by multiple scientific studies around the world, as well as in meta-analyses (De Wolff and Ijzendoorn 1997). Interestingly, although secure children often protest during separations in the SSP, secure children were more able to endure short separations in the home, such as if the caregiver switched rooms, and showed less negative affect during the home visits than children who were subsequently classified as insecure (including avoidant). Meta-analytical research has indicated that about two thirds of children tend to be securely attached in normative samples, with lower rates in children from high-risk groups (van IJzendoorn and Sagi 1999).

Secure attachment should not be mistaken for “dependency.” All children are dependent; what matters is if children are effectively or ineffectively dependent. Secure children, being effective in getting what they need from others, having their emotions accepted, and being taught flexible emotion regulation through constructive dyadic regulation with their caregiver(s), tend to develop many positive characteristics. Securely attached children, as a group, have, for example, been shown to be more independent in preschool, to become well-liked by their peers, to be rated as having high social competence, to be empathic, to show less behavior problems of both an internalizing and externalizing kind, and to have low levels of anxiety (see ► [“Effects of Attachment Quality and Organization”](#)).

Missing pieces and current research. Although the correlation between sensitivity and attachment is well established, meta-analytical research has failed to replicate the strong association that Ainsworth initially found, a phenomenon called the “transmission gap” (De Wolff and Ijzendoorn 1997). This may have several reasons. First, both attachment and sensitivity are hard to examine, and few studies have examined sensitivity as thoroughly as Ainsworth did, often settling for a few minutes of observation of play in a laboratory or naturalistic environment. However, the transmission gap has also yielded an interest in other dimensions of caregiving besides sensitivity. Caregiving attributes such as mind-mindedness and reflective functioning in relation to the child’s mind have been shown to predict child security over and above the effects of sensitivity (e.g., Fonagy et al. 2008). Another issue pertains to the mechanism(s) mediating the association between variations in attachment quality and subsequent development. That is, although secure attachment is consistently associated with a multitude of positive developmental outcomes (such as high social functioning), there are several hypotheses regarding the mechanism(s) mediating these associations, and it is currently unclear whether any mechanism is particularly important or if attachment quality and organization should be seen as a factor having broad effects on a multitude of such mechanisms

(see ► [“Effects of Attachment Quality and Organization”](#)). Lastly, although Bowlby argued that the attachment system is active and functional throughout life, he did not devote as much effort into its functioning in adult relationships, which are typically symmetrical (see ► [“Attachment in Adulthood”](#)).

Conclusion

Secure attachment is predicted by sensitive caregiving and is the pattern of attachment that is considered optimal (e.g., of highest quality), as seen in these children’s flexible and balanced organization of behavior in relation to the caregiver. That is, having internalized secure affective-cognitive representations of self and others (IWMs), secure children are able to use their caregiver both as a secure base from which to explore the environment and as a safe haven to return for comfort when distressed. Secure attachment is associated with positive socio-emotional and cognitive development.

The phenomenon whereby individuals in a socially monogamous union pursue additional sexual partners

Introduction

Biologists have long known that monogamy is rare in the animal world, especially among our fellow mammals. But biologists didn't have any idea how truly rare it is until DNA fingerprinting was applied to animals, in the 1990s. For decades it has been the received wisdom among ornithologists that 92 % of bird species were monogamous. With the advent of DNA fingerprinting, however, along with extended field studies, it became evident that social monogamy is not equivalent to sexual monogamy, i.e., that many animals seek extra-pair sexual partners while retaining their social partner.

Extra-Pair Copulations

Over time, however, a new realization dawned: social monogamy – in which a male and a female court, spend time together, and set up joint house-keeping – is not the same as sexual monogamy, i.e., limiting copulation to one's social partner. Hence the term extra-pair copulations (EPCs) was born, now a standard concept in animal behavior research, as studies employing DNA fingerprinting have revealed, time and again, that even those species that seemed devotedly monogamous were only socially so. Depending on the species, it is common to find that from 10 % to 60 % of avian offspring are not fathered by the mother's social partner (Barash and Lipton 2002).

Biologists were not surprised to find evidence that males are prone to sexual gallivanting. After all, even though the basic biology of sperm makers doesn't quite mandate searching for and when possible indulging in multiple sexual partners, it clearly inclines males of most species in that direction, simply because for males – including male *Homo sapiens* – additional mating partners means additional opportunities for fitness enhancement. What was perplexing, however, was the finding that females – even those in apparently stable domestic unions – were similarly disposed. It's just that they are more secretive about it. As a result, biologists would spend hundreds of hours carefully watching the behavior of

a mated pair without seeing any indication of sexual infidelity by the female – not necessarily because she was sexually faithful to her mate, but because she was hiding her EPCs, not from researchers, but from her social partner. Why was she doing this? For reasons not dissimilar from why socially monogamous human beings are comparably secretive when it comes to their own EPCs.

Downsides of EPCs

Evidence has accumulated from a variety of animal species that if and when the male finds evidence that “his” female has been associating with other males, he is prone to do the animal equivalent of refusing to provide child support, no longer provisioning or defending the offspring, presumably because they might not be genetically his. This pattern has been found in certain mammals (Richardson and Coetzee 1988) as well as birds (Cezilly and Nager 1995). And although there do not seem to be any data dealing explicitly with the effect of suspected adultery on divorce in human beings, common sense suggests a very close relationship.

There are remarkably little reliable DNA data on the actual frequency of human extra-pair paternity, despite the fact that such testing is now widely available. Maybe this paucity shouldn’t be surprising, because of possible reluctance on the part of most men to publicly question their wife’s fidelity. As a result, the available information tends to be biased toward circumstances (such as divorce proceedings, when child support is in dispute) in which there is liable to be higher than average extra-pair paternity. In any event, the frequency of human marriages in which the husband is not the genetic father of the mother’s children ranges from as low as 0.03 to 11.8 % (Simmons et al 2004).

Reasons for EPCs

It is one thing to understand why females – of pretty much all species – hide their EPCs from

their social partners, especially if biparental cooperation is expected when it comes to rearing offspring. More mysterious is this: given the potential costs of being caught, why do females engage in any EPCs at all? Since eggs are produced in very small numbers whereas sperm are astoundingly abundant, females very rarely need to copulate with more than one male in order to be fertilized. Biologists have identified a number of potential benefits accruing to a “cheating” female, with the specifics varying with the species and, sometimes, with individual circumstances.

Here are a few of the major fitness payoffs thus far recognized:

- Increase the genetic variety of their offspring.
- Obtain more desirable (i.e., fitness-enhancing) genes for their offspring than can be provided by their social mate.
- Obtain additional resources, notably food, from their “lovers.”
- Enhance their social status by affiliating with a male who is more dominant than their current partner.
- Purchase “infanticide insurance” by inducing other males to behave parentally toward the females’ offspring.
- Explore the potential of switching from a less desirable to a more desirable partner.

There is no reason why similar considerations (obtaining additional resources, better genes, and so forth) couldn’t motivate human females, too, although in the case of women, other factors could be involved as well – which typically are not assumed to operate among animals. These causes are all “proximate,” although they each have straightforward ultimate (evolutionary) underpinnings. Moreover, although biologists have had less reason to seek explanations for EPCs by men than by women (since the biology of sperm-making provides more than enough evolutionary rationale), the following considerations could apply to both sexes:

- Retaliating for infidelity by one’s partner
- Responding to other sources of anger with one’s partner

- Short- or long-term fascination or interest in a lover
- Seeking sexual or social gratification not otherwise available in the primary relationship

Male–Female Differences

A bottom-line message is that when sexual infidelity occurs among human beings – and whether the “infidel” is a woman or man – it is because a fundamental, biologically generated polygamous inclination (polygyny in the case of men, polyandry in the case of women) has broken through the existing monogamous social structure (Barash 2016). Not surprisingly, men consistently report higher levels of sexual infidelity in marriage than do women. This, in turn, conforms to the biology of maleness versus femaleness, and with such findings as a study that encompassed 52 different countries and about 16,000 respondents, and found that men consistently expressed interest in having more sexual partners than did women (Schmitt 2003). But a male–female difference in adultery could also be due, at least in part, to the near-universal double standard, in which men are socially encouraged to be more sexually adventurous and to seek multiple partners, in order to be seen as “real men,” whereas women who are acknowledged to be similarly inclined are often denigrated as “sluts.” Some men, as well, may be liable to exaggerate their number of infidelities, just as some women may be inclined to understate theirs.

It is pretty much a cross-cultural universal that men intimidate their spouses to refrain from extra-marital sex, punishing them – often severely and, not uncommonly, lethally – should they do so. Aside from their internal motivations, women may be most prone to “cheating” under the following circumstances:

1. When they have the support of their own relatives, which is especially likely in societies that are “matrilocal” – that is, when women live near their extended families – as opposed to “patrilocal” societies, in which following marriage, the bride moves in with her husband’s

family. Most human societies are patrilocal, which means that a wife is surrounded by her husband’s kin. This makes it easier for a man to keep tabs on her and itself facilitates a double standard (it is quite possible that patrilocality became the most common marital living arrangement precisely because it serves to discourage a wife’s infidelity, thereby reassuring husbands).

2. When wives don’t rely very heavily on their husbands for material support, protection, and assistance in child-rearing. Cross-cultural studies have found that among societies in which women get most of their sustenance from relatives, rather than from their husbands, they are more likely to have extramarital affairs and are also more prone to divorce (Flinn and Low 1986).
3. When their husband is less “desirable” than others who are sexually available, with “desirability” assessed either biologically or socioeconomically.

There is a growing body of experimental evidence suggesting that women partake of a “dual-mating strategy,” consisting of both long-term and short-term tactics. The former involves establishing a bonded relationship with a consistent partner, typically someone able to invest sufficiently in offspring and also predisposed to do so, whereas the latter calls for responding positively – especially when ovulating – to men who are literally perceived as “sexy,” which is to say, possessing good genes. Evidence for this dual strategy comes largely from a diversity of studies showing that when they are most fertile, women are especially predisposed to prefer images, sounds, and even smells arising from men who are higher in testosterone and who possess greater body symmetry – in short, who are likely to offer “good genes” (Gangestad et al. 2005).

Even though advances in contraception have enabled women to free themselves from the reproductive tyranny that had previously restricted their sexuality, it is safe to say that the great majority of women are less liberated than basic fairness would prescribe.

Change and the Future

Nonetheless, change is, ironically, the most reliable human constant, if not in our biology, then in its cultural accompaniments. In February, 2015, South Korea's Constitutional Court – citing the country's changing sexual mores and a growing emphasis on individual rights – struck down a law that for more than six decades had made adultery a criminal offense, punishable by up to 2 years in prison. Share prices for a leading Korean condom manufacturer, *Unidus*, immediately rose by nearly 15 %, and *Hyundai Pharmaceutical*, which markets so-called morning-after birth control pills, rose in value by nearly 10 %.

Conclusion

Individuals – whether male or female – who are part of a socially monogamous relationship not uncommonly seek extra-pair partners. The adaptive significance of this behavior differs for males and females, with the fitness payoff for males primarily involving additional opportunities for fathering offspring, whereas for females, the evolutionary payoffs are more diffuse but nonetheless real, notably including access to resources and seeking “better” genes for one's offspring.

Individuals (or groups) working together for a mutual benefit.

Introduction

“Many of the benefits sought by living things are disproportionately available to cooperating groups” (Axelrod and Hamilton 1981, p. 1391)

Cooperation involves individuals (or groups) working together for a mutual benefit, often at an initial cost to each participant, although the benefits from cooperation ultimately outweigh the costs to individuals. Cooperation is associated (conceptually and empirically) with altruism – behavior in which an individual forgoes a benefit to assist another. Some degree of altruism is necessary (at least initially) for cooperation to occur. To cooperate, an individual must initially give up a benefit. Altruism becomes cooperation when two or more individuals join in giving up benefits for a common goal, which they typically perceive as greater than the cost of the benefits they gave up. Our focus here is on cooperation among humans – in particular, the selection pressures (ultimate causes) that stimulated cooperation among our ancestors, the mechanisms (proximate causes) that enable cooperation to occur, and the cues people use to select other individuals as cooperative partners. What is

unique about human cooperation is that humans cooperate *widely* with other humans to whom they are *not related*. This ability to cooperate with non-kin has been critical to the complex division of labor, the widespread growth of civilizations and nation-states, large organizations, and national and international economic systems.

Selection Pressures for Cooperation

Throughout the course of human evolution, people faced selection pressures favoring interdependence and cooperation (Tomasello et al. 2012). Climate change in Africa about 2.5 to 3 million years ago likely created resource pressures on early hominids by reducing jungle and increasing savannah areas (Handwerk 2014). The capacity to cooperate probably became instrumental in helping hominids adapt to these patchier resource environments (e.g., by making foraging more successful). As humans left Africa and began to populate the globe, they encountered different environments than they had grown accustomed to, again requiring increased cooperation to survive. With the spread of humans, there was undoubtedly greater competition from other groups, adding further adaptive pressure for cooperative traits and institutions. These pressures most likely created feedback loops reinforcing cooperative behavior for both individual and group survival.

Mechanisms for Cooperation

Many species engage in cooperation among kin, which is commonly known as *kin selection* (Hamilton 1964). An allele promoting helpful behavior toward kin, even at a cost to one's self, could readily evolve and remain evolutionally stable. By helping relatives (who share one's genes), an individual can get more of his or her genes into the future. Thus, individuals should be motivated to cooperate with kin to maximize their inclusive fitness.

Cooperation among non-kin has been more difficult to explain, because it is usually in the actor's best interest to behave selfishly when interacting with non-kin. *Reciprocal altruism* (Trivers 1971) provided a plausible mechanism to explain helping behavior among unrelated individuals: People help one another when they expect that the behavior will be returned in kind. Two basic forms of reciprocity have been described. The simplest form, direct reciprocity, is a tit-for-tat cooperative strategy in which two individuals exchange cooperative acts and cease cooperating if either party defects (Axelrod and Hamilton 1981). In contrast, indirect reciprocity involves cooperation based on reputation (Nowak and Sigmund 2005). Reciprocation is indirect when it is given by someone other than the initial beneficiary. In this case, individuals help those who are known to have been helpful to others. Thus, individuals must cultivate a reputation for being cooperative if they hope to receive the benefits of cooperation.

Circumstances in which cooperation is most critical (e.g., natural disasters, wars, and famines) are those where reciprocity-based cooperation is least likely to occur. Why help someone in these circumstances, because it is unlikely that he or she will be around to return the favor? To address this problem, the theory of *strong reciprocity* suggests that humans are predisposed to cooperate and punish non-cooperators even at their own personal cost (Gintis 2000). Thus, a trait of "cooperativeness" must have evolved and been selected for so that humans are inclined (some more than others) to be cooperative.

Cooperators could have been taken advantage of by selfish individuals within their groups, making selection for cooperativeness unlikely at the individual level. Therefore, prosocial traits and behaviors must have been beneficial at the group level. Although cooperativeness can be costly to *individuals* and may be disadvantageous within groups (i.e., individual selection), cooperation increases the fitness of *groups* relative to other groups (i.e., group selection). This is the logic of *multilevel selection* theory (Wilson and Wilson 2007). Cooperation allows groups to outcompete less cooperative groups, making

cooperative individuals more likely to survive and reproduce. Integrating the perspectives of strong reciprocity and multilevel selection, Bowles and Gintis (2011) suggest that a genetically based predisposition to cooperate most likely coevolved alongside social institutions and cultural norms that reduce within-group competition (e.g., food sharing, monogamy) and help maintain cooperation, making groups that adopted those institutions and norms more successful than those who did not.

The transition from kin selection to reciprocal altruism to large-scale cooperation among non-kin is not well understood, although probable paths have been proposed (e.g., Tomasello et al. 2012). One possibility is that as kin-selection consolidated among early humans, associated cognitive and emotional mechanisms facilitating cooperation developed apace (e.g., prosocial emotions). These psychological mechanisms then might have generalized to small-scale cooperative practices among non-kin (e.g., cooperative breeding). As cultural learning and institutions (e.g., religion) became more widespread, these too reinforced cooperative sentiments and practices.

Identifying and Selecting Cooperative Partners

Cues signaling trustworthiness are important in selecting partners who are likely to cooperate. Trust cues can be categorized as personal or situational (Thielmann and Hilbig 2015). *Personal trust cues* are characteristics of a potential partner that may provide information about his or her trustworthiness. These include aspects of outward appearance, reputational information, and social category information (e.g., ingroup versus outgroup). *Situational trust cues* are features of the situation that may make someone more or less trustworthy (e.g., temptation to betray, sanctions for betrayal).

People use readily accessible verbal and non-verbal cues to judge others' trustworthiness (i.e., personal trust cues). For example, people readily infer others' (un)trustworthiness based on aspects of their faces, including its basic features or

structure, emotional expressions, and similarity to the judge's own face. Altogether, research suggests that faces are judged more trustworthy when they look happy (rather than angry), feminine (rather than masculine), mature (rather than young), and similar to the target's own face (Todorov et al. 2015). All of these facial cues appear to have adaptive significance. For example, a similar face may be a cue of kinship, a happy face may suggest that someone is approachable, an angry face may suggest that someone has harmful intentions, and a wide, masculine face may suggest that someone has the physical stature necessary to carry out their ill-intentions. Although people make trustworthiness judgments based on facial cues quickly and show high agreement in their judgments, these judgments tend to be inaccurate (Todorov et al. 2015).

People may also use reputational and social category information as personal trust cues. Individuals are more trusting of people with positive reputations than those with negative reputations (Thielmann and Hilbig 2015). Reputational information about someone can be acquired directly by observing their behavior as well as indirectly via gossip. Additionally, people are more trusting and cooperative toward strangers who are ingroup members. Thus, cues that signal ingroup membership should make someone a more attractive cooperative partner (e.g., clothing, tattoos, tribal scars).

When selecting a cooperative partner, it is wise to consider not only characteristics of the partner, but also features of the situation that may impact his or her trustworthiness. Thus, *situational trust cues* include characteristics of the social context that may make someone more or less trustworthy. The two most well-studied situational trust cues are temptation to betray and sanctions for betrayal (Thielmann and Hilbig 2015). Temptation to pursue selfish interest at the expense of mutual interest is inherent in cooperative situations, and cooperation becomes less likely the more the benefits of betrayal outweigh the benefits of cooperation. On the other hand, sanctions for betrayal (e.g., punishment or diminished reputation) can be expected to elicit more trustworthy behavior and cooperation.

Conclusion

Cooperation helped our ancestors overcome threats to survival and is a large part of the reason why *Homo sapiens* has flourished as a species. Researchers have proposed several complementary reasons why cooperation may be so widespread in humans. Ultimately, we cooperate to promote our own genes, and we do so by helping our kin, cultivating mutually beneficial social exchanges, enhancing our reputations, and because the momentum of genetic and cultural evolution compels us to. These mechanisms bear on our everyday psychological tools for identifying and selecting cooperative partners who are likely to help us achieve our goals.

The strength of natural selection on mortality and fecundity varies across ages.

Introduction

The insight that natural selection should be weaker with age was originally proposed by Ronald A. Fisher (1930) in *A Genetical Theory of Natural Selection*. In this groundbreaking book, Fisher fused Charles Darwin's theory of natural selection with Gregor Mendel's theory of particulate inheritance – a fundamental insight in the modern synthesis in biology. Fisher, however, did not fully explore how the force of selection differs across ages. That exploration would have

to wait for decades, when biological theorists (Medawar 1952; Williams 1957) realized that weakening in the force of selection with age could explain how evolution not only could – but should – result in aging: the decrease of fecundity or increase in mortality with age. Soon thereafter, William D. Hamilton (1966) provided theoretical clarity on the issue by explaining mathematically how the strength of selection varies across age groups. Age-dependent selection continues to be a topic of considerable interest, largely in research on aging and life-history theory, which addresses how organisms adapt to unpredictable versus stable environments.

Historical Origins

Ronald A. Fisher (1930) and John B. S. Haldane (1941) first proposed that the strength of selection should vary depending upon age, and more specifically that it should be weaker as adults get older. Fisher (1930) suggested that the reduction of strength of natural selection with increasing age results from the related reduction in reproductive value – the number of offspring an organism is likely to have summed across the current age and all later ages. Reproductive value is at its maximum value until reproduction begins, at which point it reduces throughout adulthood.

Age-Related Selection and Aging

Inspired by Fisher's insight about change in reproductive value over the lifespan, the biologist Peter B. Medawar (1952) made an early attempt to explain the evolution of aging in which he argued that selection should act less at later ages because of the cumulative effect of mortality across ages. That is, by assuming that death rates and reproduction rates are constant across age, a population will have a demographic structure that is comprised of more younger than older adults, with smaller and smaller proportions for older and older age groups. In this demographic structure, younger adults will produce a larger proportion of offspring each year than older members of the

population – and therefore younger individuals will contribute more genes to the next generation – resulting in stronger evolutionary selection upon younger than older individuals. Medawar therefore argued that genes whose effects were expressed earlier in life would experience stronger selection, whereas genes expressed very late in life would experience little to no selection. Medawar observed that wild animals infrequently live so long as to suffer from aging, so selection would be unable to eliminate harmful mutations that would be expressed at ages later than death usually occurs in the wild (see also Haldane 1941). The resulting buildup of deleterious mutations would cause aging when expressed in individuals living in safe environments, such as in a lab or a zoo.

George C. Williams (1957) also attempted to explain aging based on age-specific strength of selection. He argued, in particular, that strong selection early in life but weaker selection later in life would result in populations carrying pleiotropic genes – specifically genes with beneficial effects early in life but detrimental effects later in life. The harmful effects of pleiotropic genes in late life, Williams argued, would result in aging.

Building largely on the work of Fisher (1930) and Williams (1957), William D. Hamilton (1966) made explicit the mathematics underlying the intuitions of others about how the strength of selection varies across ages and therefore results in aging. In particular, Hamilton improved upon Fisher's proposal that evolutionary forces work on reproductive value. For example, Hamilton showed that a population that is decreasing in size fast enough has stronger selection on older than younger individuals (Charlesworth 1980). Hamilton demonstrated mathematically how the strength of natural selection on survival and fecundity varied across ages during the life cycle.

Hamilton's Forces of Natural Selection

Hamilton's (1966) analysis identified two scaling factors for how the strength of selection changes across the lifespan: a survival factor and a

fecundity factor. Rose and colleagues (Rose et al. 2007, p. 1265) referred to these factors as "Hamilton's Forces of Natural Selection," equating their importance for biology with Einstein's contributions for physics. The survival factor looks at "the fitness impact of an individual's future reproduction" across different ages (Rose et al. 2007, p. 1266). Its value is at its maximum of 1 before sexual maturity, 0 once reproduction ends, and decreases with age between those values. This factor looks at how much of an effect natural selection can have on the survival probability of an age group. For example, natural selection has a strong effect on the survival probability of prereproductive ages and no effect on the survival probability of ages after the cessation of reproduction (the 0 value once reproduction ceases), should such ages exist in a species. As per Rose and colleagues (2007), this force "has to decline throughout adult life until the last age of reproduction, after which the force of natural selection is zero for all remaining ages" (p. 1272). The second factor is age-specific fecundity. As per Rose and colleagues (2007), "the force of natural selection acting on fecundity . . . declines with age until the last age of survival in the population's evolutionary history" (p. 1272). That is, the second factor evaluates how much natural selection can influence the fecundity of different age groups. A common result is that selection can strongly influence the fecundity of younger age groups but has less effect on the fecundity of older age groups.

Hamilton's forces have some notable limitations and implications. When describing the death rates of humans, Hamilton (1966) suggested that the death rates should asymptote as the curve approaches the end of reproductive years. However, in humans the curve goes too far to the right (people live too long), especially for women. Hamilton agreed with Williams (1957) that the most likely explanation is parental care provided by mothers and grandmothers. This explanation is now referred to as the "grandmother hypothesis" and is also used to explain human menopause (Lahdenperä et al. 2004). By helping the survival and reproduction of kin in late life, selection would continue to work on mortality late in life

and thereby increase the lifespan. Thus, although he did not incorporate parental care (or grandparental care) into his formulas for the strength of selection across ages, Hamilton acknowledged such care as another potential way for selection to act on different age groups.

Hamilton also addressed why infant mortality is so high in humans. He suggested that in general selection should drive deleterious effects to be expressed later in life (when they are less detrimental to fitness). The exception in the human case arises because offspring with deleterious genetic effects prohibit parents' fitness and the children's own inclusive fitness (the genes it shares with relatives, another idea for which Hamilton provided the definitive mathematical statement; Hamilton 1964). For example, Hamilton suggests that a child who dies at 10 years of age wastes more parental effort than one that dies soon after birth or even soon after conception. For children with a gene that is likely to result in death, by dying earlier in life the child can be replaced by another sibling and thereby increase inclusive fitness.

Finally, note that both forces of natural selection can have declined to the point of being zero, but that survival and fecundity rates themselves need not also be zero. This means that at sufficiently old age, aging itself stops – that is, mortality rates no longer increase – and fecundity rates no longer decrease (Rose et al. 2007). Given that both forces of natural selection are strong only in early life and eventually reduce to zero, natural selection should only result in somatic adaptations that are beneficial either for young individuals or for individuals across all ages; that is, bodily adaptations for late life are not expected (Rose et al. 2007).

Evidence

Charlesworth's (1980) review found substantial evidence supporting age-specific effects of genes that are consistent with Hamilton's forces, but some anomalous findings as well. He considered five aspects of cross-species comparisons. First, strong supporting evidence is found for the

presence of aging in species which separate soma and germ cells. Second, correlational evidence supports Hamilton's scaling factors, such as species with greater external mortality – death due to uncontrollable dangers such as predators and disease – also aging faster. Third, species such as large reptiles, amphibians, and fish in which fecundity increases with age can live very long lives, as Hamilton's theory predicts. Fourth, aging should begin immediately after reproductive maturity because of one of Hamilton's scaling factors is constant before that point then decline. This is consistent with the reduced survivorship of humans immediately after puberty, the point in the lifespan of humans with the lowest mortality. However, the high juvenile mortality rates in many species are not anticipated by this theory. Fifth, for species in which reproduction ends before death, selection should allow deleterious genes to build up, but human females live after menopause. As mentioned above, Hamilton suggested this might be because they gain inclusive fitness by caring for children and grandchildren.

Implications

Diverse consequences result from the unequal strengths of selection across the lifespan and its relation to change in population size. One of the most important is that natural selection results in aging (e.g., Williams 1957). Another set of consequences are embodied in life-history theory, the idea that species (and individuals) that face relatively high rates of external mortality emphasize earlier-life reproduction at the cost of investing in growth, bodily maintenance, and parental investment (Del Giudice et al. 2015). This shorter-term strategy makes sense in unstable environments where long-term investments are unlikely to pay off.

Conclusion

Although Fisher (1930) had the insight that selection weakens as adults age, a full understanding of

how natural selection on mortality and fecundity varies across ages did not arise until theorists attempted to explain how evolution would result in aging (Medawar 1952; Williams 1957). In particular, Hamilton's (1966) mathematical treatment of the strength of selection not only provided a firm ground for addressing the evolution of aging, but laid the foundation for the major evolutionary perspective provided by life-history theory.

Instrumental Behavior	Coordinated movement of a whole living organism that, in the genetic and/or experiential history of the organism and the presence of cues correlated with the presence of a specific class of adaptive problem, caused systematic (predictable) environmental change.
Behavior	The “coordinated responses of whole living organisms to . . . stimuli” (Dugatkin 2014, p. 7).

Introduction

“If you root yourself to the ground, you can afford to be stupid. But if you move, you must have mechanisms for moving, and mechanisms to ensure that the movement is not utterly arbitrary and independent of what is going on outside.” So opens Patricia Churchland's classic (Churchland 1989) (p. 13) *Neurophilosophy*. Although the

truth of this is obvious, all too often Psychologists forget it. In seeking the short-term gains of a science of the mind, the field pays long-term costs of isolating Psychology from the well-established natural and life sciences and from factors driving evolution both in phylogenetic and ontogenetic time. Consider the following exchange between Endel Tulving and Henry L. Roediger, III (Roediger III 2004),

It is quite clear in 2004 that the term ‘psychology’ now designates at least two rather different sciences, one of behavior and the other of the mind. They both deal with living creatures, like a number of other behavioral sciences, but their overlap is slim, probably no greater than psychology or sociology used to be when the world was young. No one will ever put the two psychologies together again, because their subject matter is different, interests are different, and their understanding of the kind of science they deal with is different [We are aware that this is an argumentum ad ignorantiam]. Most telling is the fact that the two species have moved to occupy different territories, they do not talk to each other (any more), and the members do not interbreed. This is exactly as it should be. (Passage quoted in Roediger 2004)

The purpose of this chapter is to highlight a long-term cost Evolutionary Psychology pays by isolating itself from Behavioral Psychology and the long-term benefit obtained by embracing it.

We can say, like primitive man, that the existence of the mind is to be inferred from human (or animal) activity; we can say, strange as it may appear to the Behaviorist, that mind is itself, and always has been, simply a theory of behavior (Hebb 1934).

Solving adaptive problems requires functional action. Those actions include both private (observable only by the actor) and public (observable by others) behaviors. In a sexually reproducing species, taking action is necessary for genes to pass from one generation to the next. Given that fact, it is obvious that selection pressures operate *directly* on the *functional efficacy* of behavior when an organism faces adaptive problems. It is equally obvious that evolution by Natural or Sexual Selection does not occur without differences (variation) in how well behaviors solve specific classes of adaptive problems. Finally, because behavior is necessary to realize differential reproductive success, understanding

the organization of behavior and the forces that shape it is an essential component of understanding biological evolution.

In light of the facts above, a separate entry on the “implications for behavior” is somewhat baffling because, properly structured, Evolutionary Psychology (EP) focuses equally on the brain, cognition, the organization of behavior, and proximate/ultimate models of the relations among them. Orthodox Evolutionary Psychology, however, has married itself to a cognitive psychology that, while investigating matters of mind, ignores the organization of behavior.

This marriage of Evolutionary Psychology to this form of cognitive psychology rests on the assumption that “Natural selection does not operate on behavior per se” (Tooby and Cosmides 2016, p. 15). The marriage additionally assumes the existence of (physically-instantiated) cognitive-developmental *programs*, best characterized through information-processing theory, that generate unspecified but flexible and plastic adaptive behaviors. These assumptions lead Evolutionary Psychologists to focus on descriptions of the algorithmic structure of hypothetical *adaptive programs* composed of complex sets of instructions and to consider behavioral-level descriptions inadequate to capture species-typical adaptations (Tooby and Cosmides 1992).

In contrast, following James’ (1907/2013) and Peirce’s (1905) *pragmatic* approach to scientific psychology (see Baum 2017), we argue that (1) the information-processing approach to cognition is at best an awkward way to describe adaptive behavior as functionally contingent on ecological contexts (see Gladden and Jacobs 2019), (2) an information-processing approach to cognition, which is based on what philosophers call *naïve realism*, awkwardly assumes the (predesigned) “...existence of informational categories in the environment” (Edelman 1987, p. 43), independent of a receiver that has “...computational programs in the brain that can produce a broad range of plastic adaptive behavior” (Edelman 1987, p. 43) in response to those hypothetical (fictional?) informational categories. In so doing, current Orthodox EP overtly

rejects (and even disparages) a “natural” theoretical partner, a partner based on thoroughgoing *selectionist* theory.

Orthodox EP has, at its core, Darwin’s three fundamental principles: Trait variation, differential reproductive success, and trait inheritance. The theory does not specify mechanical cause-and-effect relations that occur in proximate time. Instead, the theory is pragmatic and statistical, noting trends that occur typically over many generations (i.e., the aggregate effects of many instances of mechanical causes).

Our current understanding of the organization of specific behavioral types (classes) makes use of the same principles. According to Orthodox Behavioral Theory, the organization of instrumental behavior rests on constrained behavioral variability (base rates), differential success (e.g., reinforcement; punishment), and inheritance (changes in probability of the behavioral variant exhibited resulting from experiential history). As with Darwinian Theory, the principles operate pragmatically and statistically (probabilistically), not mechanically. Although the theory may serve to guide those interested in proximate interactions that produce variability, differential success, and inheritance, the mechanisms governing them remain outside of the current domain of the theory.

Adopting such a view opens Evolutionary Psychologists to a much broader perspective. For example, examining the basis of “decision making” (exhibiting one form of behavior over another) in terms of experience with ultimate *and* proximate adaptive problems or the degree to which a specific form of instrumental behavior “solves” a complex of adaptive problems (bringing the behaving organism closer to differential reproductive success) or the proximate/ultimate adaptive costs and benefits of exhibiting one form of behavior over another. Answers to questions such as these, of course, will be found in the phylogenetic history of the organism and some within its ontogenetic history, all of which can be done without dulling Occam’s Razor by importing extraneous ill-specified theoretical terms or structures.

As with orthodox EP, orthodox (radical) Behavioral Psychology does not attempt to specify hypothetical “internal” or “external” proximate *mechanisms* because each is a descriptive science, one that does not make distinctions between internal (private) and external (public) events. Both Behavioral and Evolutionary Psychology reject dichotomies that divide the causes of behavior as if those located in the organism’s internal environment differ in some fundamental way from those located in the organism’s external environment. Both recognize that all well-organized behavior results from interactions of organisms with environments. Both acknowledge that extant behavior results from a relatively long evolutionary history and a relatively short developmental history of successfully dealing with adaptive problems.

It is of some interest that critics accuse both of attributing behavior solely to internal causes (EP) OR external causes (Behavioral Psychology). Characterizing a behavioral approach as blank-slate like because it, “. . .proposes conditioning mechanisms that apply to all situations” (Tooby and Cosmides 1992, p. 37) or asking, “Does the mind consist of a few, general-purpose mechanisms, like operant conditioning, social learning, and trial-and-error induction. . .?” is a mischaracterization.

The orthodox study of behavior qua behavior makes no assumptions about “general purpose” or “content independent” mechanisms *at all*. Instead, it studies how the organization of behavior changes in light of available behavioral variation, differential behavioral success, and inheritance of “successful” behavioral organization relative to the suite of extant adaptive problems. In short, Behavioral Psychology studies behavioral evolution in ontogenetic time (Skinner 1981).

Deconstructing a Common Misconception

B.F. Skinner (1966, 1981) was a pragmatic evolutionary-selectionist thinker who rejected the blank slate view and equipotentiality assumptions:

No reputable student of animal behavior has ever taken the position that the animal comes to the laboratory as a virtual tabula rasa, that species' differences are insignificant, and that all responses are about equally conditionable to all stimuli. (Skinner 1966, p. 1205)

From a pragmatic perspective, useful descriptions are done at various levels of analysis, without being “incoherent” about the (currently unknown) neuro-cognitive mechanisms. Baum (2017) answered a common complaint about the modern Behaviorists' assertion that many mentalistic terms are both fictional and failures as explanatory constructs:

A common response to this argument is to suggest that attitudes, beliefs, wishes, and the like exist as things in the brain. The present level of understanding of the brain, however, allows no such assertion. Perhaps someday the working of the brain will be well enough understood to shed light on the mechanisms underlying studying for an examination or robbing a store, but that day appears to lie far in the future, if it will ever arrive at all. Behavior analysis needs to wait on discoveries about the nervous system no more than physiology needed to wait on discoveries about biochemistry. Nowadays cell function is often explained with biochemistry, but physiologists understood cell function with concepts like membrane, osmosis, metabolism, and mitosis before chemists were any help at all. Similarly, behavior analysis can understand behavior at the level of interaction with the environment without any help from neurophysiologists. Indeed, when help from neurophysiologists is forthcoming, behavior analysts will have described the phenomena that could be explained further by reference to bodily mechanisms.

By the same argument, behavioral analysts understand behavioral organization at the level of interaction with functional classes of adaptive problems without necessary help from information-processing theorists. Much like Evolutionary Psychologists, modern Behavioral Psychologists focus on creating theoretically useful descriptive concepts that serve as elements in a descriptive, predictive, and useful scientific description of behavioral organization and how it evolves.

A Natural Relation Between Modern Behavioral and Evolutionary Theory

Accepting a Darwinian/selectionist view permits both modern Behavioral and Evolutionary

Psychologists to consider overt (e.g., instrumental) and covert (e.g., remembering, planning) behavior as plastic phenotypes subject to pressures exhibited by short- or long-term adaptive problems. In so doing, a whole array of selectionist theory and technique becomes available to study the full gamut of behavioral, physiological, cognitive, and emotional traits from a common and well-integrated perspective. Moreover, the apparently natural relation between Modern Behaviorism and Evolutionary Psychology provides the EP with a view that permits these plastic phenotypes to lead evolution – as factors that contribute to the variability so necessary for the development of novel traits, to new directions of change, and thereby to influence the course of evolution (see West-Eberhard (2003), for a comprehensive review).

For Evolutionary Psychologists interested in either short- or long-term evolution, modern Behavioral Psychology offers a relatively well-integrated set of descriptive theories that permit deep thinking about the evolutionary history and significance of processes influenced by extant adaptive problems presented by the environment. Indeed, Pontes et al. (2020) have provided a striking demonstration of this principle. They began with self-replicating, nonlearning, immobile digital organisms within environments that contained adaptive problems (trail nutrients) promoting the evolution of (1) navigation and (2) associative learning. The “organisms” were equipped with three familiar characteristics: they reproduce passing on any evolved traits to their offspring (trait inheritance); the process of passing on these traits could involve random mutations (variability), and individual fitness depends on how well the organism solves extant adaptive problems (differential reproductive success). Assuming that associative learning is a *phenotypic* characteristic of behavior that may be described or implemented independent of a specific set of mechanisms, these authors demonstrated that the original sessile ancestors evolved to use trail nutrients as cues, that behavior evolved from preexisting behaviors in a predictable sequence, and that a specific cognitive structure evolved depending on the stability of

adaptive problems (and solutions) that the digital organisms could exploit. Adaptive problems that remain stable across generations produced reflexive (“instinctual”) behaviors; adaptive problems that varied across phylogenetic time but remained stable in ontogenetic time built upon such reflexes and led to the evolution of two forms of associative learning. In addition, a basic “value system” appeared to evolve that permitted associative learning by gauging experience as positive (reinforcement or benefit) or negative (punishment/penalty or cost) feedback for instrumental behavior. In each case, behavior was a fundamental part of the evolution of higher-level cognitive traits.

But What About the Brain and Information Processing?

The late Gerald Edelman (1987, 1992) argued that selectionist approaches to brain development and function (“Neural Darwinism”) outperform information-processing (IP) approaches at both proximate (mechanistic) and ultimate (statistical) levels. Edelman sees information-processing approaches as failing to account for perceptual categorization, in part, because they implicitly assume an organism is *instructed* by *preexisting* categories of information that necessarily exist external to the individual and independently of its perceptual machinery. “Processors of information,” Edelman (1987) writes, “...must have information defined for them *a priori*” (p. 43), just as computers demand clarity, precision, and explicitness (Pinker 1997/2009) to process information reliably. In other words, if the brain works by processing external information, that external information must already be organized for objectively “meaningful” perceptual categorization, independent of the individual interpreter.

Assumptions that divide the hypothetical causes of behavior into classes that exist external to the organism (“information”) and those that exist internally (algorithmic “programs”), information-processing is based in philosophical realism rather philosophical pragmatism (Miller 2016). Evolutionary psychologists might imagine

that selection processes created a complex set of internal “programs” that enable organisms’ brains to respond to adaptively relevant categories of information effortlessly. But “At one stage or another of such models...,” Edelman writes, “...one sees evidence of typological thinking or essentialism – the positing of prior categories either in the environment or in the brain or in both” (p. 43).

Having identified information-processing models of brain function as instructionist and essentialist, Edelman (1987) uses evidence drawn from cognitive psychology to argue that perceptual categories are neither fixed nor closed, and, given that information-processing models of brain function require both, these models must be wrong. He notes three major features of perceptual categorization that he regards as incompatible with information-processing models: First, he describes evidence that perceptual categories are not veridical, but rather are adaptive and modifiable by context. “The very same object,” he notes, “may be classified differently at different times [e.g., a table may be used for eating in one context and as a dance floor in another], and an animal may use different means to classify that object at different times [e.g., the table may be used as a bedding area at another time]” (p. 30). Second, Edelman notes that perception involves the capacity to generalize category membership on the basis of only a few examples. Referring to Herrnstein’s (1979, 1985) work demonstrating such an ability in pigeons, Edelman argues this capacity must be independent of language. A third feature of perceptual categorization that Edelman claims is incompatible with an information processing view of perception is that, for most perceptual categories, the classical view of category “representations,” as defined by a precise list of necessary and sufficient features (e.g., a grandmother must be a female and be a parent of a parent), does not account for how people classify entities or events. Most perceptual categories are polymorphous sets, where context affects the contents of the categories. To qualify for membership in such a set, an element must satisfy a specified number, but not all, of the rules governing membership in the category.

Edelman concludes that these three features of perception "...together strongly challenge any logic-based or 'information driven' explanation of the data" (p. 30). He argues that the evidence shows that perceptual categories are created only *after* environmental signals are received, because of evolutionary selection and/or because of experience. Therefore, he concludes, the necessary a priori code assumed by information-processing models cannot exist.

Edelman sees a clear analogy between perceptual categories and the Darwinian view that species are changing and adaptable entities rather than the fixed categories of the essentialist. Noting that computers and other electronic devices must be precisely wired to function properly, he argues this variation "...would doom any equivalent parallel computer to produce meaningless output even with the best of error correcting codes" (p. 42). In other words, due to the environment being "unlabeled" (undifferentiated), contextualized, and because of variable and novel environmental changes, an organism with evolved information processing machinery would not produce appropriately flexible adaptive behavior. Instead, Edelman sees this variability as precisely what would indicate a machine that is, through behavior, tightly tied to both recurrent and variable adaptive demands, operating through processes governing differential reproductive success rather than that of an information processing machine.

But What About Cognitive Psychology and Information-Processing?

In his concern for with what goes on in the [organism's] mind, Tolman has neglected to predict what the [organism] will do. So far as the theory is concerned, the [organism] is left buried in thought. Guthrie (1935), p. 72
...it behooves a so-called 'cognitive theorist'...to explain how his intervening cognitive and motivational variables ever issue into actual behavior... Tolman (1955), p. 315

Information processing is a useful tool that may well describe important characteristics of actions such as remembering, perceiving, or feeling,

which, in the cognitive literature, bear category names like memory, perception, or emotion. The user of such a tool, however, runs a risk of reaping small short-term benefits of popular description at the large cost of theoretical coherence, scientific integration, and the benefits of cross-boundary scientific cooperation. Put another way, information processing may provide cognitive psychology with a parochial view, a light that shines brightly on specific modes of description but a light that fails to illuminate the whole contextualized broader picture: the coordinated organization of behavior, cognition, brain, and the evolutionary history of the species under study.

One problem with light shone on a specific target is that it produces biases, leaving too much in the dark. There is a large cognitive literature on implicit biases, for example, almost none of which asks, "How would a system of this form improve the differential reproductive success of our ancestors?" Likewise, the massive cognitive literature examining remembering fails to ask, "How does remembering, acting in these ways, enable organisms to out-reproduce their neighbors?" Without an overarching guidance and constraint both from the statistical properties of a central theory (i.e., selectionist theory) *and* mechanical properties of the theory underpinning it (Anatomical and Physiological theory), cognitive psychologists remain free to characterize or mischaracterize the systems that evolved to in response to selective pressures and that organize behavior in a way that permits evolution to proceed.

Among Evolutionary, Behavioral, and Cognitive psychology, modern Cognitive Psychology appears to be the odd man out. Both Evolutionary and Behavioral Psychologists use deeply related selectionist models to account for the organization of directly measurable (e.g., instrumental) and indirectly measurable (e.g., cognitive) behavior. In contrast, modern Cognitive Psychology uses an informal version of "information" processing theory to account for the behavioral organization they infer (e.g., reasoning, acquiring, consolidating, storing, retrieving "information," etc.) and appear to reify at least some of these hypothetical constructs (e.g., memory, acquisition, consolidation, storage of information).

Conclusion

EP and modern Behavioral Psychology are both pragmatic approaches that rely on descriptive selectionist models to account for behavior. Contrary to claims, both approaches reject a “blank slate” view of organisms’ inheritance. Both approaches reject the false dichotomies of nativism versus environmentalism and of internal versus external causes of behavior. In contrast, modern Cognitive Psychology embraces an instructionist (antiselectionist) information-processing approach and is grounded in a philosophical realism that assumes we can meaningfully divide the proximate causes of behavior between “prearranged” external informational categories and internal information-processing programs (complex sets of instructions instantiated in the brain) that enable the brain to interpret those hypothetical environmental categories reliably and correctly. EP needs to bring a most necessary ingredient of reproductive success-behavior-back to the center of the field to have a selectionist partner at the proximate-ontogenetic level to complement its selectionist approach at the ultimate-phylogenetic level. It is time for a productive reconciliation between two selectionist approaches EP and contextual Behavioral Psychology to create an Evolutionary Behavioral Psychology that includes an essential component of evolution, that of behavior.

Introduction

Theories and models of attention differ in a number of ways, as they attempt to explain how and when an individual processes the physical and semantic aspects of their environment. Early selection models of attention suggest that stimuli pass through a filter before they can be attended to and processed for meaning. Broadbent (1958) investigated this idea of early selection by using a split-span, or dichotic listening paradigm. In the dichotic-listening paradigm, participants are presented with two different auditory stimuli (one in each ear) at the same time and are instructed to attend to one or both of the stimuli. Afterward, they are asked about the content of either the message they were asked to attend to or the message that they were told to ignore. Broadbent found that participants had increased accuracy when asked to recall stimuli presented in the same ear than when asked to recall stimuli presented in each ear, suggesting that the information was filtered based on physical characteristics of the stimuli (such as pitch, direction, or the

ear in which the information was presented). According to this model, stimuli that are presented are held in a preattentive state and must be either selected for relevance and processed for meaning, or filtered out as irrelevant. All semantic processing of the stimuli takes place after being filtered and selected for attending. In essence, the information selected has no meaning during the selection process.

However, this model must be an incomplete explanation. Cherry's (1953) work found that participants receiving stimuli in both ears, attending to one message in one ear, were able to detect their name from the unattended ear. This is defined as the "cocktail party effect": the ability to detect significant stimuli in a multi-talker situation. This unattended-to information gained attention and was processed for meaning, which contradicts the idea of selection based on basic characteristics, rather than by meaning.

Late selection models of attending indicate that information is selected after processing for meaning. Gray and Wedderburn (1960) hypothesized that if early selection models were correct, then the presence of other, conflicting information presented at the same time in the same ear would be able to disrupt recall of information. In their study, participants were given a mixture of words and numbers presented in each ear. For example, in the left ear, participants heard *mice – 5 – cheese* and in the right ear, *3 – eat – 4*. If the early selection model was correct, then participants should have reported all stimuli presented, grouped by ear. However, they found that participants reported information grouped by type: *mice, eat, cheese* and *5, 3, 4*. This suggests that stimuli were selected according to meaning, not basic characteristics.

Memory selection models of attending merge the early and late selection models. They follow the principle of early selection that stimuli are selected based on physical characteristics, but also that of late selection: that attended and unattended information both pass through the filter to be processed for selection based on meaning. Meaning, not the filter, decides the focus of attention. Deutsch and Deutsch (1963) suggested that meaning is assigned based on importance,

and that important stimuli will be processed, placed into memory, and then on to awareness thus, only important stimuli will be remembered. In this model, all information is processed, but only information deemed important will be available for later recall.

The attenuation model of attention disagrees with the idea that stimuli must pass through a filter and that the filter decides what stimuli pass into awareness. Treisman (1969) proposed that while an early selection filter exists, the filter attenuates, or weakens, stimuli that are unattended. If stimuli are to be attended to, they must surpass a threshold to leak through the filter. This threshold itself acts as a filter, in that important words (such as an individual's name) pass through relatively easily, whereas unimportant words (such as *chair*) have greater difficulty in passing through the filter.

The multimode model of attention adheres to the notion of a flexible filter, whereby what kind of selective attending is used is dependent on what is needed at the time. In this model, both physical features and meaning can be used for selection, based on their costs and benefits. Johnston and Heinz (1978) found that as the perceptual-processing system shifts from early to late, it collects more information from unattended sources but requires more capacity to focus on an attended source. In their study, participants performed a listening task and a reaction-time (RT) task at the same time. The listening task required participants to either attend to a single list or to a target list of two or three lists. The RT task required the detection of light signals and was used to measure the amount of capacity devoted to the listening task. Longer RTs implied more capacity expended on listening. In the first condition, the target and nontarget lists differed in voice (a male or a female), but were similar in meaning. In this condition, faster response times were recorded than those in the second group, implying that early selection was able to be used due to processing based on physical characteristics (i.e., voice, direction). In the second condition, the two lists were spoken in the same voice but differed in meaning. In this condition, response time was longer, implying that early selection could not be used and late selection was necessary due to the difference in meaning.

Conclusion

Each of these models differs slightly in when exactly meaning is derived and attending occurs. To review, in early selection models, information must pass through a filter before either meaning or attending. In late selection models, information is processed for meaning and then attending may follow. Memory selection models hold that all information, regardless of attention, will pass through the filter to be processed for selection based on meaning. In the attenuation model, information is filtered, but is attenuated instead of completely filtered in or out. If information is perceived despite being attenuated, then it may be attended to and continue to have meaning extracted. In the multimode model, selective attention varies according to the individual's needs at the time, and can use the processes outlined in early, late, memory, and attenuation models of selective attention. Each of these models, however, retains the idea that some mechanism restricts the flow of all information being attending to at the same time. In addition, regardless of when meaning is eventually attached, all information requires meaning to differentiate it and activate perceptual processing.

The tendency for individuals to readily process and focus on information pertaining to survival and successful reproductive practices.

Introduction

In today's world, individuals are constantly faced with numerous avenues where cognitive resources can be distributed. However, our cognition remains peculiarly attuned toward processing the types of problems our Pleistocene ancestors faced. While individuals in modern society do not often experience the specific issues of our grassland ancestors, our memory and attention systems

evolved under this context and thus seem to demonstrate superior processing for these types of adaptive problems. Adaptive problems are those that provide challenges to an individual's survival or ability to reproduce. For example, the possibility of starvation, presence of predators and disease, and competition in procuring a mate are all threats to an individual's well-being or opportunity to produce offspring. The current review explores research on memory, attention, and emotions, providing support for the notion that human cognition is attuned to the adaptations developed to aid in survival under the earliest human conditions.

Human Cognition and Survival Threat

Inspiring a field of research combining evolutionary and cognitive psychology, Nairne et al.'s (2007) research on the survival processing effect demonstrated the memory advantage for processing items according to their grassland survival relevance. In a typical experimental evaluation of this mnemonic effect, participants are asked to rate a list of words for their relevance to the individual's ability to survive in a foreign grassland – including the need to find food, water, and protection from predators – or for their relevance to a control condition (e.g., moving homes to a foreign land where a house and transportation must be obtained). A surprise recall test is then completed where participants attempt to remember as many words as possible from the rating task. Furthermore, the survival processing conditions have been pitted against intentional learning conditions, in which participants are specifically instructed to remember words for a later memory test. Even when compared to intentional learning, words processed in an ancestral survival context are remembered to the greatest extent (e.g., Nairne et al. 2008).

This robust adaptive memory advantage has been well-established. A heightened memory for survival related concepts has been shown to occur when considering survival in isolation (e.g., stranded alone in a foreign land) or within a group (e.g., stranded with others in a foreign

land), as well as in both ancestral contexts (e.g., lost in a jungle) and unfamiliar scenarios (e.g., lost in outer space) (Kostic et al. 2012). While the underlying mechanisms of the effect are not yet fully understood, other known mnemonic devices such as self-reference, semantic relatedness, and elaboration have all been shown to play key parts (see Kazanas and Altarriba 2015 for a recent review). Once the concept of survival is activated, it appears to recruit a slew of memory mechanisms to achieve an adaptive end of preparing and reacting to potential threats (Nairne and Pandeirada 2016). Through an increased memory for adaptive problems, an individual is better able to seek out solutions that perpetuate life and avoid death. For example, it would be beneficial to remember where to find potable water and which color of berries is poisonous. The benefit of a memory that is keen for promoting survival by engaging various other mnemonic mechanisms allows the individual to actively maintain his or her life.

While remembering has its obvious advantages, the ability to selectively forget information is also beneficial. A healthy memory is naturally attuned to retaining positive, self-affirming information while disregarding instances that threaten the self-concept (Nørby 2015). Human memory has developed to be self-protecting as a means to ignore information that cannot be changed and could otherwise cause personal distress (e.g., maintaining an embarrassing childhood experience). Positivity is associated with comfort and is most often an indication of a safe environment. By selectively creating memories that fit the characteristics of a preferred environment, cognitive resources are able to be spent on true threats, such as avoiding predators and starvation, which can be planned for and dealt with accordingly.

To encode information into memory, attention must first be paid to the stimulus in question. What type of information best captures attention? As discussed, stimuli that allows for the detection and processing of potential danger and benefit is given a high priority in human cognition. Emotional stimuli often have a high adaptive value because they provide a large amount of information about the environment. In a recent study by

Fernández-Martín et al. (2017), participants viewed pairs of scenes while their eye movements were recorded. As compared to neutral scenes (e.g., flowers or mushrooms), individuals tended to look at pleasant visual scenes (e.g., babies and families) first. This inclination toward pleasant stimuli indicates a positive orientation bias. However, negative visual scenes (e.g., mutilation or weapons) were more often assessed for a longer period of time than either positive or neutral scenes. This indicates a negativity engagement bias such that negative information is harder to withdraw or disengage from. Furthermore, when images were presented centrally in front of the participant, males were more likely to orient their vision toward scenes depicting opposite-sex and couple erotica (i.e., reproductive focus) while women more readily looked at images of illness and loss (i.e., nurturer and caregiver roles). The authors concluded that visual attention is automatically drawn toward emotional images, particularly those that coincide with an individual's domain-specific or sex-specific goals. The heightened attention toward emotion, particularly negative emotion, serves as a mechanism for individuals to readily identify and extract information that will most benefit the individual within his or her adaptive roles.

From an evolutionary perspective, emotions have evolved to assist in solving a range of problems to include: signaling danger and disgust; indicating levels of mood, energy, and effort allocation; and prioritizing motivations (Al-Shawaf et al. 2016). Memories from experiences that elicited a negative emotion are indicative of situations that should be avoided in the present and future. However, positive emotions tend to motivate approach behaviors, as individuals tend to seek feelings of safety and comfort (see Elliot and Covington 2001, for a review of approach-avoidance motivation).

Directing attention toward emotionally arousing stimuli can serve adaptive purposes for self-survival, but also for procreation. From an evolutionary perspective, humans have an innate drive to not only preserve their life, but reproduce and maintain their genes through offspring. For both sexes, there is an attunement toward attractive

individuals. Maner et al. (2007) showed participants images of male and female faces and recorded their eye-movements. When presented images of highly attractive persons and neutral-attractive persons, individuals of both sexes not only looked at the attractive faces longer, but they had the most difficulty disengaging their attention from the attractive female faces. The authors argued that for men, this attunement serves the purpose of identifying prospective mates. For women, detecting potential threats to their current or future partner is an important component of securing and maintaining a mate. In this case, the potential concern for mate poaching is at hand, where individuals seek to engage with individuals known to already be in a romantic relationship (see Davies and Shackelford 2015 but see also Buss et al. 2017 for a discussion on mate switching). The ability to quickly recognize individuals who may be potential mates or competitors is an adaptive strategy to improve one's chance of reproductive success.

Conclusion

As discussed, the systems composing human cognition have developed to readily process information pertaining to survival. This ability to quickly identify possible sources of threat and procure safety and mates allows the individual a greater chance at maintaining life and passing on their genes. By allocating cognitive resources to survival, individuals have evolved memory, attention, and emotional systems that coordinate to be best fitted for solving adaptive problems.

Definition

Males are likely to be equipped with psychological mechanisms for estimating their own fighting ability, thereby enabling them to compare their own ability to that of competitors and to opt out of interpersonal conflicts in which their likelihood of success is low.

Introduction

Interpersonal conflict, particularly among males, can be quite costly in terms of risk of injury. Individuals are likely to be equipped with psychological mechanisms for self-assessment of fighting ability in order to determine whether to participate in the conflict as a function of their predicted likelihood of success. The likelihood of success is estimated by combatants through the approximations of one's own strength relative to those with whom they are in competition. The strategies that are employed in order to gauge the fighting prowess of the self and competitors have been observed and documented by a number of studies. This entry will describe how humans, particularly males, estimate their own strength and fighting ability.

Evolutionary Foundation

Human aggression is most commonly deployed against and by males (Daly and Wilson [1983](#)). In

this way, humans conform to a widespread mammalian pattern in which the sex that invests less in offspring competes more aggressively for access to mates and the resources used to keep and acquire them (Daly and Wilson 1983). This prediction is borne out of parental investment theory (Trivers 1972). Parental investment refers to any expenditure by the parents that is meant to aid the offspring at the cost of the parents' own potential reproductive opportunity. Given the inherent time and energetic costs of reproduction undertaken by females during the gestational and postnatal periods, large constraints are placed on females' reproductive capacity. This shifts women's mating strategy to one that prioritizes long-term mating and investment, rather than short-term. Conversely, males' obligatory investment in offspring is fulfilled at the time of conception, thereby creating a reproductive ceiling that is limited only by their ability to access mating opportunities. This shifts men's mating strategy to one that prioritizes short-term mating with minimal investment in each offspring.

This dimorphism between the sexes is the precursor to sexual selection. Females, being the primary investors in offspring, are discriminating in their mate selection, thereby evoking intrasexual competition among men who seek to gain reproductive access to many females. This competition creates large variability in the reproductive success among men, such that a few men may monopolize many females, leaving other men with few to no mating opportunities. The potential for reproductive oblivion escalates the intensity of intrasexual competition among men, often turning the competition into violent conflict. Such mating contests present the potential for a highly valued benefit, but also carry very real costs in the form of the risk of injury or death.

Minimizing Costs of Competition

The risk entailed in violent conflict is amplified when males compete with men to whom they are vastly outmatched. Even among the most formidable men, there are costs of suffering physical injury which can impair their ability to fend off

future attacks, hunt, build shelters, etc. Moreover, any interpersonal conflict carries opportunity costs, in that individuals who are spending time fighting or healing from injury are not using that time to promote their fitness through other activities. It would have therefore behooved males to be able to accurately estimate their probability of winning such a contest. Lower probabilities of winning may be tolerated by men who are most in danger of reproductive failure. This is consistent with data presented by Daly and Wilson (1985) showing that rates of male-male homicide are particularly elevated among men who are unmarried and/or unemployed. Men may therefore be equipped with psychological mechanisms that calculate the expected utility of engaging in an interpersonal conflict. A key element of this calculation is an estimation of the likelihood of winning the contest which requires the ability to compare one's own fighting ability to that of a competitor.

Perceived fighting ability is used as a gauge in order to determine the likelihood of emerging victorious in a potential fight. As males are the primary combatants in physical confrontations, it logically follows that they would have adapted methods for estimating the formidability of their competitors in relation to their own in order to properly gauge risks and rewards of confrontation.

Due to the nature of prediction, there is a trade-off between the accuracy and cost of the assessment. For example, one can estimate fighting ability very well by fighting someone to the death, but that comes at a great price. On the other side of the trade-off are perceptual estimates of fighting ability that are energetically cheap and do not risk injury but provide less precise assessments. Although not perfect, research suggests that these assessments are valid indicators of fighting ability (Sell 2016) and may therefore serve as a primary source of information in the decision of whether or not to engage in a physical contest.

Characteristics of Rival Assessment

Information about the physical capabilities of an adversary is useful in that it can inform one's self-

assessment of fighting ability. An essential aspect of self-assessment lies in rival-assessment. For example, early in childhood, young boys engage in a great deal of rough-and-tumble play (Daly 1994) that establishes a status hierarchy among boys and provides each individual with information about how their own fighting prowess compares to that of their peers. This hierarchy persists into adolescence and adulthood, changing as members become more or less formidable. Research suggests that the reason for this could be that this preference helped ancient hominids to estimate the costs, rewards, and outcome potentials of ingroup and outgroup aggressive conflicts.

A number of cues are perceived that can aid in the assessment of physical prowess. These cues are read as indicators of formidability of an opponent with regard to potential future altercations. Most definitive among perceived cues are those that provide information about an individual's upper body strength. This is because upper body strength is the single best predictor of someone's fighting prowess. Most human fighting requires several techniques for hitting or grappling, all of which rely primarily upon upper body strength. Upper body strength can be inferred from a number of traits that provide cues to observers to help them approximate the strength of a rival. For example, facial features predict a quarter of the variance in upper body strength, particularly among male raters, when rating male targets (Sell 2016). The structure of the face has been formed through evolutionary processes and carries with it indicators of upper body strength. These facial clues include roundness of the face, eyebrow width, and the prominence of the jaw (Windhager et al. 2011). Another cue that is predictive of upper body strength is the acoustics of the voice. According to Sell et al. (2010) listeners consistently attribute higher estimates of size and strength to men with lower pitched voices. Despite this, the pitch of a person's voice is very limited in its predictive capability. It is thought that the vocal pitch is influenced by the vocal folds that are highly reactive to testosterone and therefore highly sexually dimorphic, which leads people to infer that more dramatically dimorphic voices must also be physically dimorphic and stronger.

Characteristics of Self-Assessment

Research investigating the mechanisms that make self-assessment of fighting ability possible is still in early stages. However, high correlations between self-assessments and objective measures of strength have shown that humans can store and update a representation of their own formidability (Sell et al. 2009). This representation is updated whenever new experience or knowledge is gained pertaining to one's prowess. A lost fight, for example, can lead to a more modest estimate of one's prowess. It is this estimate, the estimate of one's own fighting ability, which allows costs and benefits to be compared through a visual assessment of a rival. Because men are significantly more likely than women to assess their own fighting ability without provocation (Buss 2016), it is inferred that they maintain a hierarchy and acknowledge their place within it. These unprovoked assessments are common because men are regularly updating their hierarchical positioning. Cues that are observed to assess the formidability of an opponent presumably could play a role in the self-assessment of formidability. However, such cues would not have been as readily accessible to ancestral humans, owing to a lack of modern technology (e.g., mirrors for self-reflection). Thus, cues to their own upper body strength would need to be indirectly inferred.

Evidence of self-assessment must be inferred through observation of conflict and pre-conflict behaviors. Males will attempt to appear larger than they are when facing rivals in order to intimidate them. When a competitor knows that they are outmatched by a rival, they will back down rather than escalating conflict. Nonhuman animals have been observed engaging in "conflicts of assessment" (Huntingford and Turner 1987; Alcock 2005) that allow the animals to ritually size up their competition before engaging in physical confrontation. This leads to a reduced chance of injury for both parties. Other animals have also been observed to win perceived contests with dummy rivals and thus perceived themselves as more capable. This led to them being more likely to challenge a real rival in future confrontations (Sell 2016). What this tells us is that animals are

not only estimating their own prowess, but they can also update these estimates as they gather more information and experience much the same way that humans do.

This sizing up has also been observed to allow individuals to assert their fighting prowess and avoid conflict by driving a foe to submission before any escalation of conflict. For example, red deer have been observed to employ roaring contests before engaging in conflict (Clutton-Brock et al. 1979). These rituals provide an extra gauge for the rivals to finalize their assessment of each other in reference to their own self-assessments and make a final determination regarding the risk and rewards of contest.

Conclusion

Homo sapiens have adapted numerous ways of determining the likely outcome of confrontation before ever engaging in said confrontation. This ability is greatly beneficial, as it allows them to estimate both the risks of confrontation as well as the likelihood of gaining access to potential benefits (i.e., resources, access to mates, etc.). This is particularly prominent among males as they are known to be the primary instigators of conflict as they engage in competition for resources. Knowing this, it can be extrapolated that males in particular have adaptations for assessing their own fighting ability and updating this assessment as new information and experience are introduced. Further research will most likely be directed at estimating aggression based on perceptions of the physical characteristics of the self and rival alike.

Self-Beneficial Political Attitudes

Definition

Across a range of evolutionary relevant political domains, humans seek to advance tangible fitness-related goals.

Introduction

Politics is about “who gets what, when and how” (Lasswell 1950). At the heart of politics is the regulation of access to resources and the distribution of them (Easton 1965). Politics can take place in species where individuals have interest conflicts about the rules regulating the distribution of resources and have cognitive capacities for a sense of social regularity (Petersen and Aarøe 2015). This article focuses on self-beneficial political attitudes in humans.

From an evolutionary perspective, the existence of politics across species suggests that biologically instantiated psychological mechanisms evolved through natural selection underlie political behavior. Evolutionary psychologists have mapped a wide range of domain-specific cognitive mechanisms designed to assess the distribution of costs and benefits “within and between groups from the perspective of the self” (Petersen and Aarøe 2012, p. 804). To the extent that modern political issues reflect evolutionary recurrent problems such as resource sharing with needy individuals, deterrence of exploiters, relationships with outgroups, and

warfare, evolved cognitive mechanisms should be expected to shape modern political attitudes (Petersen and Aarøe 2012, p. 804). An evolutionary perspective highlights that humans are equipped with a political psychology that is *ecologically rational*, i.e., optimized to operate efficiently in the face of recurrent adaptive problems and maximize reproductive fitness in the ecology of ancestral life (Petersen et al. 2014).

The Classic Puzzle About the Influence of Self-Interest on Political Attitudes

In the political science literature, Thomas Hobbes, one of the founders of modern political philosophy, identified self-interest as a fundamental human motive shaping political behavior (1651/1950). The notion that individuals are self-interested optimizers is also the cardinal assumption in modern rational choice theory on political preference formation (see Chong 2013 for an overview). Importantly, in a number of studies, the influence of self-interest on policy preferences has often been relatively weak (e.g., Sears and Funk 1991). Outlining the state-of-the-art view in the political science literature, Haidt (2012, p. 100) sums up: “Many political scientists used to assume that people vote selfishly, choosing the candidate or policy that will benefit them most.” But decades of research on public opinion have led to the conclusion that self-interest is a weak predictor of policy preferences (see also Weeden and Kurzban 2014, p. 28). The limited influence of self-interest in empirical studies of political attitudes represents an important puzzle in the public opinion literature.

An Evolutionary Approach to the Concept of Self-Interest and Political Attitudes

In the political science literature, self-interest has often been defined in relatively narrow, short-term economic terms as “the tangible, relatively

immediate, personal or family benefits of a policy” to avoid conceptual challenges of separating different sources of interests (Chong 2013, p. 101; see also Sears and Funk 1991). In the political science literature, scholars often emphasize this narrow conceptualization and measurement of self-interest as part of the explanation for the limited influence of self-interest found in many public opinion surveys (Chong 2013).

An evolutionary approach to the study of public opinion and preference formation highlights the relevance of a wider conceptualization and a biologically informed understanding of self-interest. From an evolutionary perspective, self-serving goals can go beyond the short-term and economic benefits (e.g., Kenrick et al. 2010; Kenrick and Griskevicius 2013; Weeden and Kurzban 2014, 2017). An evolutionary approach to political attitude formation views humans as political animals equipped with psychological mechanisms designed to solve adaptive problems and pursue tangible goals that ultimately increase survival and reproductive fitness (e.g., Weeden and Kurzban 2017, p. 75; Petersen and Aarøe 2015; Kenrick et al. 2010). As explained by Kenrick and Griskevicius (2013, p. 9), “as in the case of all other animals, natural selection has endowed modern humans with brains designed to make decisions in various domains in ways that consistently enhanced our ancestors’ odds of passing their genes to the next generation.”

Humans can increase their reproductive success by achieving a range of subsidiary typical goals representing distinct domains of adaptive behavior. The human mind is equipped with multiple domain-specific motivational systems designed by natural selection to solve adaptive problems that have been recurrent over human evolutionary history and in this way advance evolved strategic goals. Typical subsidiary fitness-enhancing goals include social status, resources, affiliation, mates, and parenting (Kenrick et al. 2010; Weeden and Kurzban 2017). In this view, self-serving political attitudes include not only positions that are consistent with short-term economic interests. Rather they can reflect “a range of people’s typical goals, whether directly involving material gain or not, whether involving immediate gain or something that

advances someone’s progress over the longer term” (Weeden and Kurzban 2014, p. 37).

Genetically Selfish Goals and Inclusive Interests

An evolutionary perspective highlights that organisms are ultimately motivated by genetically selfish goals (Dawkins 1989; see also Weeden and Kurzban 2017, p. 75). Organisms seek genetic reproduction either through their own reproductive success or through the reproductive success of individuals carrying the same genes. From this perspective, “self-interest” can be understood to include both the self and close kin. Drawing on the concept of “inclusive fitness” (Hamilton 1964) which in evolutionary biology refers to the combined gene-level reproductive success of an organism and its relatives, some scholars have therefore suggested to “jettison the term self-interest altogether” and replace it with the notion of “inclusive interests” (Weeden and Kurzban 2014, p. 38).

The Debate Over Self-Interest and Political Attitudes Continues

Weeden and Kurzban’s (2014, 2017) wider definition of self-interest and their concept of inclusive interests have been criticized for being too broad. Critics argue that the wider definition lacks clarity with respect to what would count against the argument that self-interest is often a major determinant of political attitudes (e.g., Caplan 2015). In response, Weeden and Kurzban (2015) have highlighted that their point is not that self-interest is the only factor in public opinion but that there is no reason to reserve the term self-interest to short-term economic interests. Thus, Weeden and Kurzban (2015) explain: “An evolutionary perspective can help highlight various strategic conflicts within societies that go beyond income redistribution, including fights over in-group preferences and conflicting reproductive lifestyles. We don’t think there’s any clear reason to call it ‘self-interest’ when one of these domains is at issue but *not* self-interest for the others.”

Conclusion

In the political science literature, self-interest has often been defined in relatively narrow, short-term economic terms as “the tangible, relatively immediate, personal or family benefits of a policy” to circumvent conceptual challenges of separating different sources of interests (Chong 2013, p. 101; see also Sears and Funk 1991). In the political science literature, the standard view is that self-interest has limited effect on political attitudes. An evolutionary approach to the study of public opinion emphasizes that self-serving goals can go beyond short-term economic interests. Humans are equipped with a political psychology that is *ecologically rational*, i.e., optimized to operate efficiently in the face of recurrent adaptive problems and maximize reproductive fitness in the ecology of ancestral life (Petersen et al. 2014).

Definition

Self-categorization theory posits that self-conception is formed through the process of *categorizing* or cognitively grouping the self, as either similar to or different from another class of stimuli. Contextual salience of various categories, ranging from personal (self-concept in terms of idiosyncratic attributes) to social (self-concept in terms of social category membership), and their relative influential strength at a given moment underlie the possibility for categorization at different levels of inclusiveness. The theory posits that different levels of self-conception are not only distinct from each other but also represent equally valid and authentic expressions of the self. Self-concept is characterized as an on-the-spot reflexive categorizing of the self in relation to an ever-changing and contextually-dependent frame of reference, which gives coherence to fluidity of the self and variation in human behavior.

Introduction

Self-categorization theory (SCT; Turner et al. 1987) has been characterized as the as “the social identity theory of the group” (Turner et al. 1987, p. 42), as it provides a social-cognitive account of *intragroup* process (e.g., group identification and behavior) through group-based construal of self and others. Self-categorization theory holds that the cognitive mechanism that gives rise to group-level processes, such as group cohesion and solidarity, is embedded in the shifting of self-concept from *personal* to *social* identity. This entry is a brief delineation of self-categorization theory’s view on self-concept, underlying factors that generate shared social identity, and how the ability to experience a subjectively *shared* self-concept could have an evolutionary advantage.

Fluidity in Self-Concept

The theory assumes that through the process of self-categorizing, one’s self-concept is generated.

Categorizing refers to the grouping of the self as identical to some class of stimuli in contrast to another. As with all natural categories, categorization can operate at varying levels of abstraction based on the process of class inclusion. Self-categorizing can occur at levels more inclusive than that of the individual level, as “we” and “us,” or at levels less inclusive than the individual, as “the real me,” or “the me I was yesterday as opposed to today.” Cognitive representations of the self are proposed to operate on three main levels of inclusiveness: the superordinate category of the self as human being (or *human identity*), a level that differentiated the self from other species; the intermediate social level of self as an ingroup member, a level that differentiated the self from outgroup members (*social identity*); and the subordinate personal level, which defines the individual as a unique person, distinct from other ingroup members (*personal identity*). The theory emphasizes that each level of self-conception is representative of a distinct, yet equally valid, and authentic expression of the self.

The process of self-categorizing is considered to vary in relation to contextual factors, as perceived similarities and differences operate in parallel to the perceiver’s self-appraisal in relation to an ever-changing frame of reference. Individuals that are perceived and categorized as different in one context (e.g., biologists vs. physicists in the science department) can be perceived as similar in a different context (science faculty vs. art faculty in a university) without any actual change in an individual’s own position. Simply put, the extension of a perceiver’s frame of reference also extends the degree to which a target person is seen to share a common categorical identity with the perceiver, in a manner predicted by the meta-contrast principle, which proposes that category formation and distinction are contingent on maximized perception of intercategory differences relative to intracategory differences (Turner et al. 1987). The perception of the self or others, as either similar or different, is therefore not fixed or based on absolute relationships, but rather determined by the level of inclusiveness that one categorizes themselves in a given context. The theory explains that as the content of self-concept

varies across levels of categorization, so will the meaning of a particular stimulus to the perceiver and subsequently their behavioral response to it. This is corroborated with evidence showing that the same information may be accepted or rejected by the same person in different social contexts, depending on how they have categorized themselves and others at the time. For example, group polarization studies have shown that the same information is rejected when it comes from an outgroup member, but accepted when it is received from an ingroup member (Turner et al. 1987).
